Sir: A hot discussion has once again arisen in England over the question of medical fees, and, in relation to fees, what are known as dispensary or cash practices. The *Daily Telegraph* has opened its pages to the ventilation of the matter, and harrowing tales are being told of the privations to which unfortunate medical practitioners are subjected in order to gain a living, together with the loss of professional dignity and self-respect, and of the state of almost degradation to which many of them are reduced in their struggle for existence. The writer can speak with experience as to the manner in which dispensary practices are worked. For a period of about a year he was in charge of one of the largest in the East End of London. There can be no doubt that the dispensary practice system in England, as it is now carried on, is a grave scandal to the medical profession, but it is difficult to conceive what the remedy for this state of affairs should be. The East End of London is the original home of the dispensary practice. It has certainly spread to the suburbs and taken root in all the large towns of the United Kingdom, but it is to the East End that one must go to view it in its highest or rather lowest state of development. When it is considered that the population of this district of London numbers something like two millions of poor people of varying degrees of poverty, it will be easily understood what a fruitful field there must be for this description of practice. It is here that the bad effects of the sharp competition among doctors is most fully shown and under its most unpleasant phases. In order to gain patients, charges are cut down to the lowest extent possible and advertising dodges of all kinds are resorted to. The outside of the office or doctor's shop, as it is termed in the East End, is made as attractive as can be. The charges for attendance are blazoned on the windows, which are large and similar to those of a druggist's store, and usually painted in some glaring color. In many instances the sum of but eight cents is charged for medicine and advice, and for a visit the charge is seldom more than twenty-five cents. Midwifery cases are treated at from three and a half dollars to five dollars. Tooth extracting, twelve cents; vaccination, twelve cents. In connection with these practices it may be mentioned that a member of Parliament, Dr. Ambrose, runs one in the Whitechapel Road. A scandal which at one time was very prevalent in the East End was the system of what is termed "covering." By covering is meant that an unqualified person occupies a house on which figures the name of a qualified man, who probably lives at a considerable distance from this house. Deaths may happen and certificates are given in the name of this surgeon, although the cases have been seen only by the unqualified man who represents himself as a doctor. This form of procedure is dying out, owing to the fact that the laws regulating the granting of death certificates are now very stringent, and partly also because there are plenty of qualified men willing and eager to take these assistantships. From the foregoing account it may occur to readers that the class of medical men in the East End of London must be of a low standard, but, whatever may have been the case in times past, it is by no means so at the present time. The men who practise there are (with but comparatively few exceptions) well qualified, better probably than the ordinary run of country practitioners. They are simply forced into this style of work in order to live, and perhaps with the hope of making enough money to be enabled to get away and set up a practice in a more desirable locality. In truth, with regard to the medical profession in England it has come to this pass, that if, when a man has qualified, he has not sufficient capital to buy a practice or exist until patients come, he must either take a wretchedly paid assistancy or start a dispensary practice in the slums. Strange to relate, fortunes are made sometimes, and quickly too, in the East End; for instance, at the branch over which the writer presided. The average weekly takings were more than one hundred and fifty dollars. Drugs are the chief item of expense, and it may be taken for granted that cheap ones are mostly used. One advantage that these cash practices have over the ordinary practice is that no credit is given. Nevertheless, when all is taken into account, the doctors who make a fortune in them are few, while the majority struggle on, leading a miserable from-hand-to-mouth existence. The reason for this unhappy condition of things is of course largely due to the acute competition caused by the supply of medical men being much greater than the demand, and at present there seems to be no reasonable hope that this oversupply will be checked to any appreciable extent. The lengthening of the medical course in Great Britain to five years and the greater severity of the examinations may serve as a slight remedy, but after all it will only be a slight one. When it is granted that the evil is largely due to competition, it must also be allowed that the *raison d'être* of the dispensary practice was the establishing of provident or self-supporting dispensaries, practitioners in the poor neighborhoods where these were introduced were compelled in self-defence so to reduce their fees as to be able to compete with them on equal terms. The question of provident dispensaries has been already pretty well threshed out, the members of the higher branches of the profession being in their

favor and the general practitioners against them. There are many arguments both for and against, and it is very difficult to arrive at a just conclusion on the matter. However, this much may be said, that while these dispensaries may have benefited the poor, they have certainly been instrumental in reducing medical fees. In the same way that co-operative stores have compelled retail tradesmen to lower their prices, so these cheap dispensaries for paying patients have reduced medical fees, and, if they continue to be conducted in the way in which they are being conducted now, must in the long run reduce these fees to a minimum. It has been truly said that everything of which the community stands in continual need has a market value except medical service, and the fault of this lies with the doctor himself. There is one point to be particularly noted, and that is that it has not been the leading men who have suffered; they can take care of themselves, but it has been the rank and file of the profession. In many districts it has led, and sooner or later it will lead, to an irremediable reduction of the already low scale of medical fees over the whole of Great Britain. If the medical profession in England had possessed the moral courage to speak out boldly on the subject of medical fees, and protested against this cheapening of its services, something might have been done. Now it is to be feared that the time for protesting has gone by. The medical men of America may esteem themselves fortunate that as yet the dispensary practice has not been introduced. If they are wise they will take warning by the misfortunes of England and take every precaution against such a system gaining a hold. It should also be remembered that the introduction of self-supporting dispensaries was the thin end of the wedge. If provident dispensaries had not been popularized, there would have been no need for doctors to advertise in their windows advice and medicine for eight cents.

London February 1, 1897.

THE INHERITANCE OF MUTILATIONS, AND OTHER INHERITANCES.

To the Editor of the Medical Record

Sir: Since the publication of Dr. Lockwood's experiments in breeding tailless mice, it rather seems accepted as true by the profession that a mutilation has but to be inflicted on an indefinite number of successive generations to insure its heredity. While this is indisputably proven regarding mice, yet facts within the observation of all cause one to doubt whether the same is true with other animals. The dehorning of cattle has been practised for quite a time, yet I have known no hornless offspring of decornutated ancestry. My own family has occupied the same lands for nearly a century—four generations. Each in succession has marked hogs with the same mutilation of the ears. Yet none has seen a single pig born with mutilated aural appendages. And it is conceded that our stock hogs are of the same general ancestry on one side, improvement being sought by changing the sire, which also invariably suffered the same mutilation. The custom of cutting off the tails of young lambs is as old as the settlement of this State, was brought hence from Virginia, where it obtained since her colonization, coming thence from England, extending I do not know how far back, at least to the era of Little Bo-Peep. I have made careful inquiry of both breeders and buyers of sheep, and have learned of but two instances of lambs born without tails. Since I have myself observed more than a like number of tailless calves at birth, I fairly reason that these were freaks of nature rather than instances of the heredity of mutilation. These examples afford fair grounds for belief that the mouse is less tenacious of racial characteristics than any other of the lower animals affording means of observation regarding the transmission of mutilations, if indeed they do not absolutely show that the inheritance of mutilations is a legacy peculiar to the mouse among all the lower animals. That there is no such inheritance in the human race, we have a proof as indisputable as can be imagined. The Jews are probably of all races the least miscegenated. They have practised circumcision since the time of Abraham. Yet by "tale or history" we know of no offspring of that race denied the said rite by reason of congenital absence of the foreskin. While the inheritance of mutilations seems exceptional, and even disproven regarding many animals from fairly extensive observation and experiment, the transmission of mental impress is much more susceptible of proof. Mr. Railey, a noted horseman of this county, had a mare and a stallion both well trained in the "high school" and "park" gaits. Their sires probably had received the same education; I know nothing as to their dams. I have seen a colt of these two go "high school" in the pasture, of his own free will and inclination, before he ever knew bit or rein. The sire in question became the property of Mrs. Joe Emmet, and is, I think, to be seen in your city to-day. Another instance of this kind of heredity has been seen by all. What is known as the "pointing" or "sitting instinct" in dogs is but the development through heredity of that ecstatic pause that the presence of quarry excites in beasts of prey. It is to be observed to a slight extent in all members of both the dog and cat family. The pause or "crouch" of the lion or tiger before springing is not so much for pose of limb for that purpose as it is the transient hypnosis from imminence of prey. This hypnosis of sight or ecstatic expectancy, developed by education and fixed by heredity, is surely the most reasonable explanation of the distinguishing characteristic of our bird dogs. It has had no development in the cat for sufficient reasons. She is the most uncivilized of all domestic animals. What she originally was and what she is now are one and the same, except as influenced by environment. The cat is unsusceptible of education. Such things as further her physical needs she takes advantage of, not from the influence of man, but merely as she would have done had she found the same conditions in nature. As I have seen elsewhere mentioned, she will rub her back against a man's legs as formerly against a tree, prefers the shelter of a fireside to that of the forest, food freely bestowed to the chances of the chase; but in native instincts she is in no wise changed or developed from her aboriginal state, and even in color constantly tends to the mottling of the mingled lights and shadows that proved her protection in the pristine forests.

S. M. Worthington, M.D.

Versailles Ky.

UPON "APPENDICITIS" AND OTHER MEDICAL BARBARISMS.

To the Editor of the Medical Record.

Sir: As all of us should do, the writer heartily approves of efforts toward a purer nomenclature. The class of men which prefers—to name a few examples—the term cœliotomy to laparotomy, colpitis to vaginitis, proctitis to rectitis, amygdalitis to tonsillitis, will not willingly continue using the word appendicitis. Nevertheless, I fear this hybrid term has become enough of a fixture to be with difficulty dislodged.

Dr. Gerster's recent letter in the Medical Record upon this subject has therefore a motive with which I am in sympathy: and as I studied surgery for years under him I hesitate to differ from a gentleman for

whom I entertain so great a respect. However, his proposition, which is that we use the words scolex and scolecitis, scolecectomy, etc., seems to me rather a waste of inventive energy, because there is already a term of pure Greek derivation covering this field, and one that is already occasionally used by purists in medical terminology.

I allude to ecphyas, meaning an offshoot (of the bowel, here), hence ecphyaditis, ecphyadectomy, etc.

The word ecphyas I have found in a very old medical dictionary in my possession, and also in the very recent ones, Foster's, for instance. The word is said to have been Galen's term for the appendix. It is fairly euphonic, I think more so than that suggested by Dr. Gerster, though possibly this may be a matter of taste; and since it is already of such established antiquity and authority, one need hardly go afield in search of another.

In order to accomplish anything, concerted action is necessary. If the members of the New York Surgical Society would agree to drop the word appendicitis and in their discussions substitute ecphyaditis (or scolecitis), that would go far toward popularizing the proper term with the profession.

Just such work is being at this time accomplished by the Association of American Anatomists, particularly in brain nomenclature.[1] Many of the more absurd terms have been dropped by them, and more correct ones unanimously substituted. As a result, the rising generation of students at all our colleges will learn, especially in neuronymy, a brain which differs so greatly in its terms from that of our day that unless we who learned our anatomy many years ago keep "brushed up" we shall not know what in the world the boys are talking about. Nevertheless, these changes in the so-called "fixed" science of anatomy are all in the right direction, and should have been made long ago. And there are many terms, too, in surgical use which might with equal propriety be overhauled in some such authoritative way.

A trifling contribution of this nature I made at a recent meeting of the New York Surgical Society, namely, in reference to the term hallux valgus, which disease was the subject of the paper of the evening. There is no such Latin substantive as *hallux* (though it is given in the medical dictionaries) but there is a *hallex*, one meaning of which is the pollex pedis, or great toe.

This little mistake in Latinity has been copied from one text-book to another continually. When first the writer noted it, some ten years ago, the point was referred to Prof. Harry T. Peck, professor of Latin in Columbia University, and he stated that hallex is the proper term. Accordingly Dr. F. J. Brockway's "Anatomy," issuing shortly after, printed it correctly; but no other has it so. The long extensor muscle of the hallex should hence be extensor proprius hallicis (not hallucis).

Of course this is a trifling point—which is why I put it at the very bottom of this letter; but we may as well be accurate.

ROBERT H. M. DAWBARN, M.D.
105 WEST SEVENTY-FOURTH STREET, NEW YORK,
February 2, 1897.

EMESIS AND INTUBATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In reply to Dr. Hubbard's letter in the MEDICAL RECORD of February 7th, on emesis and intubation, I can say positively that vomiting while a tube is in the larynx—that is, with an open glottis—is not at all uncommon, notwithstanding the teaching of physiology to the contrary. Whether this act is more difficult or not under these circumstances, I am not prepared to say, as I am free to confess that my attention had never been specially called to this subject before. It is true, as Dr. Hubbard states, that the most powerful emetics fail to act when dyspnœa is extreme, which failure he attributes to the inability to suspend respiration by closing the glottis, even for a moment. The more probable explanation of this phenomenon is the inhibitive action of carbonic-acid poisoning on the gastric portion of the vagus centre, because emetics administered without effect during the suffocative stage of croup often act vigorously when free respiration is restored by intubation and in spite of an open glottis. This was a more common experience in the pre-antitoxin days, when emetics were generally given before calling an intubationist.

The foregoing is not the only instance in which clinical facts prove physiological teaching to be in error. Foster, in describing the mechanics of respiration, says: "It need hardly be added that when the pleura is punctured and air can gain free admission from the exterior in the pleural chamber, . . . the effect of the respiratory movements is simply to drive air in and out of that chamber, instead of in and out of the lung. There is, in consequence, no renewal of the air within the lungs under these circumstances." If this teaching were true, no case of empyema with a free opening into the pleural cavity could terminate in recovery, when it is a notorious fact that these patients rarely recover without opening and drainage, and as rarely die if a free opening is made in time and maintained. Air gets into the lung on the affected side and expands it to its full capacity, in spite of an opening in the pleural cavity, however free and unobstructed.

J. O'DWYER, M.D.

CAUSE OF UNTOWARD EFFECTS ASCRIBED TO *X*-RAYS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: It has been my fortune to observe certain cases of dermatitis, loss of hair, etc., in patients who have been exposed to the action of *x*-rays. Numerous other instances of burning, depilation, and bleaching have been reported by different observers. These annoying and unlooked-for accidents tend to lessen the frequency of resort to a method of investigation which I believe to be too valuable to be thus limited. Let me, therefore, call attention to what Mr. Tesla has said in a recent number of the *Electrical Review*. He believes the evil effects are not due to the *x*-ray itself, but to the incidental formation of ozone. Since the appearance of the contribution to the *Review*, he has kindly expressed himself further on the subject to the writer. He says in a recent letter: "Since I made those statements (in the *Electrical Review*) I have gained additional evidence that the *x*-rays themselves are incapable of producing the actions reported, and that they are due to ozone and possibly nitrous acid. I wish to add that also heat may be to a certain extent responsible." He goes on to state that the effects always follow long exposures at short range, and he believes that the long-continued heat may cause desiccation of the skin, with subsequent dermatitis. As to avoiding the chemical effects, Mr. Tesla goes on to say: "I have suggested a remedy, consisting in static screening of the person in any way. The most perfect way is to make a conducting enclosure of wire or thin sheets, and connect the latter to the ground. The person should then be in that chamber, and the bulb outside of it." He goes on to say that in his experience this method will guard against ill effects. Aluminium, which is transparent

[1] See the Journal of Comparative Neurology, for example; vol. vi., No. 2, pp. 131–132.

to *x*-rays but which will not allow chemical substances to pass, might be used to make the screen.

Mr. Tesla attributes most of the reported accidents to the use of insufficient instruments, necessitating too close and too long exposures.

The writer, in confirmation of Mr. Tesla, desires to call attention to the occasional occurrence of bleaching, which is a characteristic effect of ozone.

HOWARD LILIENTHAL, M.D.

NEW YORK, February 7, 1897.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 13, 1897:

	Cases.	Deaths.
Tuberculosis	153	122
Typhoid fever	15	3
Scarlet fever	160	17
Cerebro-spinal meningitis	3	5
Measles	174	9
Diphtheria	219	38
Laryngeal diphtheria (croup)	15	7
Chicken-pox	22	0

Congenital Teeth.—Dr. J. W. Ballantyne gives an acccount of several cases which have come under his observation, also of his researches in regard to this anomaly. His conclusions are as follows: 1. Congenital teeth form a rare anomaly, but one which has long been known both to the profession and to the public. 2. Their presence has often an ill effect upon lactation, partly on account of the imperfect closure of the infant's mouth, and partly by the wounding of the mother's nipple; sublingual ulceration may also be a result, and infantile diarrhœa and atrophy are more distant consequences. Sometimes, however, symptoms are altogether absent. 3. Congenital teeth have probably little or no prognostic significance as regards the bodily or mental vigor of the infant carrying them. 4. The teeth usually met with are lower incisors, but sometimes upper incisors may be seen, and very rarely molars of either the upper or lower jaw. Other facial or buccal malformations may occasionally be met with. 5. They are caused by the premature occurrence of the processes which normally lead to the cutting of the milk teeth; in a few cases it would seem that the anomaly is due to a true ectopia of the dental follicle and its contained tooth. 6. In a few instances a hereditary history has been established. 7. As congenital teeth are usually incomplete and ill-developed, and likely to be more an inconvenience than an advantage to the infant, they are best removed soon after birth, an operation which can be easily and, except in very rare instances, safely performed. 8. The occurrence of premature teeth in certain well-known historical personages is an interesting fact, the importance of which has been much exaggerated.—*Edinburgh Medical Journal.*

Would Asexualization of Chronic Criminals, Sexual Perverts, and Hereditary Defectives Benefit Society and Elevate the Human Race?—Dr. Stuver (*Texas Medical Journal*, November, 1896) concludes his interesting paper as follows: "1st. By removing or modifying their exciting causes and favoring circumstances it (asexualization) would greatly limit the dissemination of disease, vice, and crime. 2d. It would furnish a humane and rational punishment for a large and continually increasing number of criminals, and satisfy the demands of justice. 3d. Owing to the innate repugnance toward this condition, it would be a powerful deterrent, and thereby limit the prevalence of crime and protect society against the criminal. 4th. By removing the procreative capacity of defectives and criminals, it would do more to diminish their numbers and protect society against their ravages, while at the same time raising the physical, intellectual, and moral standard of the race than all other punishments combined. 5th. It would be the humane and rational method of treating these classes, because it would protect them against harsh and brutal punishments, and by removing the cause of their obliquities transform many of them into useful and productive citizens."

Pigeons and the Plague.—It is said that the pigeons in Bombay are dying just as the rats did in the epidemic of Hong-Kong.

An Instance of Extraordinary Hereditary Prolificness.—Valenta (*Wiener medizinische Wochenschrift*, January 16, 1897, p. 103) cites an apparently authenticated case of a linen weaver's wife, forty years old, and married twenty years, who bore in eleven pregnancies thirty-two children, as follows: In the first labor, quadruplets; in the second labor, triplets; in the third labor, quadruplets; in the fourth labor, twins; in the fifth labor, triplets; in the sixth labor, twins (stillborn); in the seventh labor, triplets; in the eighth labor, triplets; in the ninth labor, twins; in the tenth labor, triplets; and in the eleventh labor triplets (two stillborn). Twenty-six of the infants were males, and six females. The father was one of twins, and the mother one of quadruplets, of a mother who had borne thirty-eight children. The woman had been epileptic from her fifteenth year, the attacks recurring unchanged during successive pregnancies. The woman was in the third month of her twelfth pregnancy when this report was made.

An Unusual Collection of Foreign Bodies in the Stomach; Removal by Gastrotomy. — Fricker (*Deutsche medicinische Wochenschrift*, January 21, 1897, p. 56) has reported the case of a woman, thirty-two years old, who, during an attack of mental aberration, swallowed a number of articles, such as spoons, forks, crochet needles, hairpins, keys, etc., some of which had been passed by the bowel, and it was thought that a number had been retained. The patient asked that she be operated upon to secure relief from her suffering. She had also lost a good deal in weight. For a period of two weeks a sensitive tumor had become apparent upon the left side of the abdomen. Its surface was smooth and its consistency firm, except at the summit, where it appeared to be softer and to yield fluctuation. When the abdomen was opened by an incision over the swelling, an abscess cavity was found, having for its posterior boundary the anterior wall of the stomach. Investigation showed that this cavity had resulted from the perforation of the stomach by a crochet needle. The stomach was next opened in an uninvolved portion, and from its cavity were evacuated the following articles: a key, two teaspoons, a fork, two pieces of wire, two hairpins, twelve pieces of glass, a window hook, a steel pen, nine sewing-needles, a piece of graphite, a shoe button, a grape seed, two beads, and the crochet needle already noted. The interior of the stomach was carefully irrigated with sterile salt solution, and the wound in its wall closed by a double row of sutures. The abdominal wound was packed with gauze, and, in the absence of complications, was closed after several days. For five days the patient was sustained by nutrient enemata; afterward the administration of food by the mouth was begun. Recovery was perfect, and the woman gained considerably in weight after the operation.

CONSTIPATION AND DIARRHŒA AS SEQUELÆ OF SOME GASTRIC AFFECTIONS.[1]

BY MAX EINHORN, M.D.,

NEW YORK.

THE digestive tract of man consists, as is well known, of a continuous tubular system, into which the stomach is inserted, forming a large sacculation. If, therefore, disturbances of the stomach and of the intestines are found associated, it will not astonish any one. In fact, certain processes often take place in the intestine as well as in the stomach. Thus, for instance, acute gastritis is frequently associated with inflammatory processes of the superior part of the small intestine. Likewise, atonic conditions of the stomach and the intestines are often met with together. Occasionally, however, the features of disease in the stomach and intestine are not of the same nature, although they are, nevertheless, dependent upon each other; or, in other words, the condition of one organ is the consequence of the disturbed function of the other.

Constipation and diarrhœa are the evident symptoms of the disturbed function of the inferior part of the intestine. Both conditions may appear primarily due to affections of the small or large intestine. Sometimes they may be associated with diseases of the stomach. Occasionally, however, they may be met with as sequelæ of chronic affections of the stomach, the large and small intestine, in reality, showing no lesion whatever. The latter conditions appear to be of great interest, first, because they have as yet not been sufficiently studied; secondly, on account of their great practical value. For this reason, permit me to discuss this subject before you.

That an abnormal condition of the chemical function of the stomach may be the cause of a faulty state of intestinal peristalsis is quite easily comprehensible; for the normal peristalsis of the gut depends, as is well known, upon certain chemical and mechanical stimuli which the chyme produces upon the ganglionic cells and nerve plexuses in the intestinal wall (the ganglions of Meissner and Auerbach). The abnormal chemism of the stomach produces new and heterogeneous qualities of the chyme, be it chemically or physically. If there be, for instance, a superabundance of gastric juice and the latter be too strong (hyperchlorhydria), then the chyme reaching the small intestine is too acid, poor in undigested albumin, and richer in unchanged starchy products. If, on the other hand, we have to deal with achylia gastrica, the albuminates, as is well known, do not undergo any changes whatever in the stomach, while free starch is converted into maltose too quickly; most of the starch being encased in an albuminous membrane, it cannot be changed before the latter has been opened. Thus the food particles leave the stomach in quite an unchanged condition and reach the small intestine in a coarse form. In this manner, there is here mechanically too great and chemically too small a stimulus.

Although these abnormal conditions are mostly corrected by the regulating mechanism which is always at the disposal of our organism—thus, in hyperchlorhydria the intestinal and pancreatic juices are probably richer in alkalies, caused by the secretion of a great amount of acid radicals within the stomach, the blood thereby becoming for a while more alkalescent, and are thus enabled to neutralize the acids of this chyme and also to change the starchy products into maltose; in achylia gastrica, on the other hand, there appears a greater activity of the small intestine, the food thereby being here more thoroughly digested—notwithstanding this, it is easily conceivable that we shall meet in these conditions abnormalities of the intestinal peristalsis more often than elsewhere, on account of the small intestine working under difficulties. Whenever the conditions are not favorable, abnormal symptoms appear.

In fact, constipation as well as diarrhœa is met with accompanying gastric affections, frequently being a mere sequela of the disturbed and altered digestion of the stomach, without any real lesion of the bowel.

When does constipation and when does diarrhœa occur?

Although there are no strict rules with regard to this point, the following statement may, however, be made: Conditions of hyperchlorhydria are often accompanied by constipation and only seldom by diarrhœa; while achylia gastrica and also severe protracted cases of chronic gastric catarrh are more frequently associated with diarrhœa.

In my paper, "A Further Report on Achylia Gastrica,"[1] I have described several cases of this affection, in which the diarrhœa was the most prominent symptom—in fact, in some instances, the only complaint of the patient. In my book, "Diseases of the Stomach,"[2] I have divided the cases of achylia gastrica in the three following groups:

"1. Patients without any subjective symptoms whatever and enjoying perfect euphoria.

"2. Patients presenting a variety of gastric symptoms associated with mild intestinal disturbances.

"3. Patients without any apparent gastric symptoms, but with severe and obstinate intestinal disturbances."

With reference to the last group, I may be permitted to give the following quotation from my book:[3]

"The third group, without gastric symptoms but with intestinal disturbances, forms, according to my experience, at least one-fifth of all the cases of achylia gastrica. In this group there may be either no gastric disturbances whatever or very slight ones (as, for instance, occasionally slight pressure in the gastric region—or belching). The appetite is either normal or somewhat increased. The principal symptom in most of these cases is obstinate diarrhœa, or diarrhœa alternating with periods of constipation. Some of these

[1] Read before the German Medical Society of New York, February 1, 1897.

[2] Max Einhorn: "Diseases of the Stomach," 1896, p. 325 (Wm. Wood & Co., New York).

[3] *Ibid.*, pp. 328 and 329.

cases present symptoms similar to those met with in diabetes: constant thirst, frequent micturition, extreme weakness, great loss of flesh: in some, however, these symptoms are less marked, or there may exist merely a feeling of weakness and lack of energy."

Oppler[1] has also recently made observations on the occurrence of these cases of diarrhœa, and pointed out the importance of a chemical examination of the stomach in affections of the intestines. This author[2] has also described the association of constipation with the condition of hyperchlorhydria, and has thoroughly discussed this subject.

As I have already remarked, I will speak this evening only of those cases of constipation and diarrhœa which must be considered as resulting conditions of a digestive disturbance of the stomach, without any real lesion of the intestines. The question presents itself: What means have we of excluding a true lesion of the intestine?

Practically, we may answer this question as follows: That when chronic constipation or diarrhœa exists, together with a disturbed chemical action of the stomach, and by a rational treatment of this organ the intestinal symptoms disappear, then can the latter be said to be conditional upon the faulty digestion of the stomach. Were the disease processes existing independently in the intestines, they could not be so quickly improved simply by correcting the functions of the stomach.

Taking this as a guide, I shall describe a few cases, which will clearly demonstrate these relations between the stomach and intestines.

Case of Hyperchlorhydria with Constipation.—Henry O——, aged eighteen years, for the last two years has suffered with tolerably severe pain in the stomach, which usually appeared about two hours after eating; there have been frequent attacks of vomiting during the last five months, and the patient has lost fifteen pounds during the past year.

Present condition: Color of lips and cheeks, white; tongue somewhat coated; lungs and heart normal. Palpation of abdomen shows no point of pain on pressure; splashing sound easily brought out in the region of the stomach. By the aid of this phenomenon one can locate the greater curvature from two to three fingerbreadths below the navel. The same is confirmed by gastrodiaphany. Knee reflex present. Urine contains neither sugar nor albumin.

Examination of the stomach contents one hour after Ewald's test breakfast shows: HCl +: acidity = 100; free HCl = 80; no remnant of food taken the day before.

The treatment consisted in giving one-half drachm of bicarbonate of sodium three times a day, two hours after eating, and in the regulation of the diet. The vomiting quickly ceased and the bowels became regular, without resorting to laxatives.

Cases of Hyperchlorhydria with Diarrhœa.—Case I.—November 12, 1891. Robert P——, aged twenty-seven years, musician. Patient was scrofulous until his ninth year, and since has always had a weak stomach: could bear no fat; always inclined to diarrhœa. In 1883 patient was confined in bed fourteen days with dysentery; afterward patient had a feeling of weakness in the limbs, with off and on a craving appetite. From 1885 to 1889 he was tolerably well; later there occurred sudden frequent stools, besides stomach complaints, sour regurgitation, flatulence, gas, but only little pain. He continued in this condition without treatment for nine months. Then the patient had a severe diarrhœa, ten movements during the night, and was treated for nine months afterward with opium. As long as he took this drug he felt very well, but as soon as he stopped the powder his weakness reappeared, combined with shivering and diarrhœa. There was always during the disease a bad taste in the mouth; appetite was usually small, occasionally alternating with craving hunger; he felt compelled to drink a great deal, particularly at meals.

Present condition: Stomach dilated. Examination one hour after test breakfast shows: HCl + traces; acidity = 100; organic acid +. The patient was given one-half drachm of bicarbonate of sodium three times a day, two hours after eating. The stomach was, besides, treated with direct faradization, according to my method.

After two or three weeks the symptoms improved, the patient increased in weight, and the diarrhœa ceased. The treatment was continued for three months, and since that time the patient has remained well.

Case II.—February 8, 1894. Frank D——, aged twenty-six years. Was always well until about two years ago, when he was taken with diarrhœa and suffered pain after eating. Vomiting was never present; there was, however, frequent eructation. The number of stools daily was from five to eight, and they were almost always of a pappy or watery character. No slime was ever observed by the patient. During these two years he lost twenty pounds in weight, and felt so miserable that he could scarcely attend to his business.

Present condition: Lips and cheeks somewhat pale: tongue slightly coated; lungs and heart normal. Palpation of the abdomen brings out tenderness over the upper part: splashing is easily demonstrated in the region of the stomach. By the aid of this phenomenon the lower border of the stomach is found to extend three fingerbreadths below the navel. The right kidney is movable and quite easily felt after deep inspiration. The urine is free from sugar and albumin.

Examination of the stomach contents one hour after Ewald's test breakfast shows: HCl +; acidity = 100; free HCl = 82.

The patient was treated with intragastric faradization, also taking half a teaspoonful of bicarbonate of sodium three times a day, two hours after eating. After fourteen days' treatment the patient had gained six pounds in weight and the movements became normal. By way of trial, the bicarbonate of sodium was omitted for a week. During this time the diarrhœa returned a few times and the patient ceased to gain in weight. The bicarbonate of sodium was again resumed, and the patient showed for two months a constant gain in weight. The diarrhœa has not appeared again, all the complaints of the patient have disappeared, and he has since remained well.

Case III.—December 6, 1896. Harry H——, thirty-two years old, was always well and robust until about a year ago. Since then he began to suffer from diarrhœa. The movements numbered five to eight daily. The patient has never observed any mucus in his stools. Patient does not complain of pains, although the latter occasionally appear in the abdomen shortly before the evacuations. The appetite is good, and there is no uneasy sensation after meals.

Present condition: Patient well developed and of strong bony structure: appears well nourished. Tongue is pretty clean and moist. Chest organs intact. Palpation of the abdomen does not reveal any painful spots on pressure. The stomach can be followed by means of the splashing sound down to two fingers' width below the navel. Knee-jerk is present. The urine does not contain any sugar or albumin.

The patient was first treated with tannigen and co-

[1] B. Oppler "Ueber die Abhängigkeit gewisser chronischer Diarrhöen von mangelnder Secretion des Magensaftes," Deutsche med. Woch., 1896, No. 32.

[2] B. Oppler: "Ueber die Therapie gewisser mit Magenaffectionen zusammenhängender Erkrankungen des Darms," Therap. Monats., 1896, No. 3.

deine (tannigen, 0.5; codeine phosphate, 0.01, t.i.d.). After a fortnight's use of this medication the patient did not feel in any way better, and his diarrhœa continued in the old manner.

December 12, 1896, examination of the stomach one hour after Ewald's test breakfast: HCl +; acidity = 104; free HCl = 80; erythrodextrin + much. The diagnosis of hyperchlorhydria is made, and it is assumed that the diarrhœa must be due to this abnormal state of the gastric chemism. The patient is given bicarbonate of sodium and sugar of peppermint āā., one teaspoonful of the powder three times daily, two hours after meals. The diet is likewise arranged as suitable to conditions of hyperchlorhydria.

The patient was treated in this way for over a month, and asserts that during all this period he felt perfectly well and that his stools were formed and normal.

A Case of Achylia Gastrica with Constipation.—June 12, 1895. Mrs. R. W——, aged about forty-three years, complained of pain in the stomach, which occurred a short time after eating. A feeling of pressure in the epigastrium was almost always present. Appetite was very defective and the bowels were inclined to the highest degree of constipation. The trouble dated back one year, in which time she had lost thirty pounds in weight. The examination showed a slight tenderness on pressure in the epigastric region and a decided anæmic condition of the visible mucous membranes; otherwise the physical examination showed nothing abnormal. The examination after the test breakfast showed: HCl = 0; acidity = 4; rennet = 0; pepsin = 0. Quantity, about fifteen cubic centimetres, in which the bread was quite unchanged and mixed with very little fluid. In consideration of the chemical analysis of the stomach contents and the absence of any tumor, the diagnosis of achylia gastrica was made as of utmost probability and carcinoma temporarily excluded. The patient was given:

℞ Tr. nuc. vom.,
Ext. condurango fl.,
Aq. amygd. amar.....āā 10
S. Gtt. xx. ten minutes before eating, three times a day, and was ordered a rich vegetarian diet.

In the course of three months the patient had gained twenty pounds in weight and was free from all complaints. Very soon after the introduction of the new regimen the bowels became regular. It was therefore quite unnecessary to use any laxatives. Notwithstanding the patient felt quite well, the condition of the stomach remained the same as before, as an examination of the stomach contents in October, 1895, showed. The diagnosis of achylia gastrica must now be regarded as a certainty.

A Case of Achylia Gastrica with Chronic Diarrhœa.—October, 1895. Samson F——, aged forty-six years, merchant, had suffered for about a year and a half with frequent attacks of diarrhœa. His appetite was good, sometimes with a feeling of hunger returning a short time (one hour) after eating. The patient had during the last year lost twenty pounds in weight and felt quite weak. A short walk would exhaust him and he was hardly able to attend to his business.

Present condition: October 15, 1895, tongue only slightly coated; lips and cheeks pale, anæmic; organs of chest normal. Palpation of the abdomen shows no tenderness in the region of the stomach. Splashing sounds brought out only after drinking of water, showing lower border of the stomach to lie two finger-breadths above the navel. Knee phenomenon normal. Urine contains neither sugar nor albumin.

The patient was treated for a long time with the usual intestinal styptic and tonic remedies, but they failed to produce any substantial result. If the diarrhœa abated for a few days, it soon returned with renewed energy. Neither was the strength of the patient in the least increased during these two months of the ordinary treatment. Notwithstanding that in this case no peculiar or marked symptoms pointed to stomach disturbance, I decided to examine the gastric secretions to ascertain thereby whether the obstinate diarrhœa was dependent upon any abnormal condition of the stomach.

On December 3, 1895, an examination of the stomach contents one hour after Ewald's test breakfast showed: HCl = 0: acid = 2; rennet = 0; pepsin = 0: biuret reaction = 0. Quantity, twenty cubic centimetres, in which there were little fluid and no mucus. Bread particles unchanged.

The diagnosis of achylia gastrica was now made and the patient treated in accordance with this condition. The diet consisted chiefly of vegetarian food with the addition of small quantities of fish or meat. Besides this, intragastric faradization was employed. After fourteen days the diarrhœa disappeared and the patient felt stronger; following that he visibly improved and after a course of three months, according to his appearance and subjective feelings, was entirely cured: besides he had gained meanwhile fifteen pounds in weight. Another examination of the stomach, one hour after the test breakfast, gave, however, a similar result as in the beginning of the treatment. About one year has now elapsed and the patient is without any trouble or complaint whatever.

Summary.—The above described cases serve only as examples and are taken at random from a large number of similar observations. Oppler has assumed, in his paper cited above, that diarrhœa is a result of achylia gastrica and constipation of hyperchlorhydria. I am of the opinion that, although diarrhœa is more often found associated with achylia gastrica and constipation with hyperchlorhydria, neither the one nor the other can be regarded as typical of these troubles. On the contrary it may easily be seen from the above-described cases that chronic constipation may result from achylia gastrica and likewise diarrhœa from hyperchlorhydria.

In reviewing the histories of the patients referred to, we see that all were improved, or rather cured, through a mere correction of the faulty chemical state of the stomach and a diet suitable to the existing condition. Not only did the symptoms of the stomach but also those of the intestines entirely disappear. In some of these cases, to be sure, intraventricular faradization was used and certainly contributed toward the improvement of the patient; still, this alone without the above-mentioned regimen would not have been sufficient. In most of the cases cited the intestinal symptoms, *i.e.*, constipation or diarrhœa, were fought by me or by others at first, without special examination of the chemical action of the stomach, by the ordinary methods of treatment, but without success. This clearly shows of what importance under certain conditions an accurate chemical examination of the stomach may be, even in cases of apparently merely intestinal complaints. It should be put down as a rule that in cases of chronic diarrhœa or constipation which do not yield to general methods of treatment, a thorough examination of the stomach, in respect to its chemical action, should be resorted to. A connection between the apparent affection of the intestines and the condition of the stomach will then be found in many cases, and a rational treatment in this way made possible.

Bubo.—Injection of camphorated salol and iodoform caused cicatrization in eighteen cases of chancroidal bubo, in from five to eight days.—Dubujadoux.

ACCIDENTAL HEMORRHAGE.[1]

By GEORGE L. BRODHEAD, M.D.,

INSTRUCTOR IN OBSTETRICS, COLUMBIA COLLEGE OF PHYSICIANS AND SURGEONS; RESIDENT PHYSICIAN, SLOANE MATERNITY HOSPITAL, NEW YORK

In the presentation of this subject for study and discussion, I feel sure that you will agree with me that we have to deal with one of the most interesting and important in the entire field of obstetrics. Accidental hemorrhage cases, as we shall see later on in the paper, are by no means so rare as many suppose. The general practitioner is sure to meet them, and on his skill and judgment depends alike the safety of mother and child. In the hospital we continually see cases which might have terminated very differently had the original line of treatment been one of active interference and not one of useless, dangerous delay. With these few words of introduction let us proceed at once with our subject, knowing that by its careful consideration we can the better understand it, and therefore be able the better to treat such cases.

Definition.—As the hemorrhage which occurs in placenta prævia and other conditions is often the result, partially at least, of accident, it is necessary first that we understand clearly just what is meant by the term "accidental hemorrhage." In a few words, "accidental hemorrhage," as the term is generally understood, means the hemorrhage resulting from or taking place at the same time with separation of a normally situated placenta.

Varieties and Pathology.—Let us now see what occurs when from any cause rupture of the uteroplacental vessels takes place. Two results are inevitable, namely, hemorrhage and separation of the placenta from its uterine attachment. Upon the extent to which these take place must depend the gravity of the case. In other words, the greater the separation and the more profuse the bleeding, the more serious the condition with which we have to deal. At first the hemorrhage may be apparently trifling, resulting perhaps from the rupture of a tiny placental vessel, weakened by chronic nephritis in the mother. But this small amount of blood, by its irritation as a foreign body, will excite contraction of the uterus, this in itself producing further separation and additional hemorrhage, now, no doubt, in greater part from the uterine sinuses themselves. This hemorrhage and separation may however remain, so to speak, localized, and no further trouble ensue. Later we shall speak of a number of cases in which a slight amount of separation took place with no apparent harm, but the tendency is certainly toward further increase, separation having once begun. There are two main varieties of accidental hemorrhage—the visible and the concealed—while cases do at times occur which belong as much to one variety as to the other, showing certain features of both classes. In the visible variety we include all those cases, mild or severe, in which the greater part of the hemorrhage appears externally; in the concealed, all those cases in which the blood remains wholly, or in larger part at least, within the cavity of the uterus. Blood may be concealed between the placenta and uterine wall, between the fœtal sac and the uterus, or may rarely escape into the amniotic sac. By the collection of a large amount of blood in the uterus, the fœtus in its bag of membranes may be pushed upward, downward, or to one side, depending to some extent on the manner in which separation has taken place. Within the last year we have seen two cases, in one of which the fœtus was crowded well up into the fundus, while in the other the placenta had been entirely separated and pushed downward with the fœtus into the lower segment of the uterus.

Frequency of the Visible Variety.—Statistics are very meagre for both mild and severe forms. Some writers think the condition a very rare one, but as a matter of fact we do meet with the mild variety, at least, not infrequently. At the Sloane Maternity Hospital there have been in fifty-nine hundred cases fifty-seven of mild accidental hemorrhage—practically one in each one hundred cases. No doubt these figures are too high for private practice, as many such patients are sent in by physicians, or come in of their own accord, to the hospital. Severe visible hemorrhage is certainly rare, even in the memory of men who have had large maternity experience. At the Sloane we have had one typical case, which we shall describe later, and which fortunately terminated well.

Frequency of the Concealed Variety.—First, in regard to the mild form, of which little mention is made in the books, but which is nevertheless of interest. We not infrequently find on careful inspection of the placenta and membranes the remains of old blood clot, when no history can be obtained of either pain or hemorrhage. In looking over the records of the last one thousand deliveries at the hospital, I find that in seven cases traces were found of old hemorrhage, in the form of decolorized, grayish, "putty-like" masses, adherent to placenta or membranes, and varying in size from a nickel to the largest, which measured three and a half by two and a half inches. These masses are thin as a rule, but in some cases measure from one-third to one-half of an inch in thickness. Of these seven cases two were slightly premature, five went to full term; there was no history of any kind in either of the cases, and six of the seven occurred in multiparæ, thus showing the predisposition to hemorrhage on the part of women who have already borne children. No better proof can be obtained than these cases to show that partial separation does not necessarily bring about the termination of pregnancy.

Secondly, in regard to the severe concealed variety, Storer, in the *Boston Medical and Surgical Journal* for 1892, collected one hundred and fifty-three cases, including those of Goodell and Hicks, and to these we shall add two which have come under observation at the hospital during the past year.

Etiology.—Causes may be either predisposing or exciting. Among the former, on the maternal side, are acute diseases, such as the exanthemata, typhoid, pneumonia, and nephritis. Chronic nephritis is also a frequent cause, of which many cases give good evidence. Again we have alcoholism, syphilis, anæmia, debility from any cause, and, last but not least, multiparity, which has been already mentioned. On the fœtal side we have hydramnion, twin pregnancy, death of fœtus and degeneration of the placenta, fatty or calcareous, with the production of fibrinous masses. Barnes, in his "System of Obstetrics," says: "Such a diseased placenta, containing solid lumps or of unequal consistency, will not follow and adapt itself to the varying movements of the uterus and changing superficial area of the placental site so easily as a healthy placenta." Turning now to the exciting causes on the maternal side we have:

I. Rhythmical uterine contractions, which in the healthy uterus would probably cause no harm, but in the presence of a predisposing factor lead to evil results.

II. Violence, such as a blow, fall, strain from lifting, coughing, vomiting, slipping, or at stool, and possibly coitus, all tending to laceration at placental site. Some authorities, such as Barnes, doubt the occurrence of hemorrhage, even from violence, without some predisposing cause.

III. Sudden determination of blood to the uterus and placental site, from emotion or shock. Sudden tension is relieved by extravasation and hemorrhage results.

[1] Read before the West End Medical Society, February 6, 1897.

On the fœtal side the exciting causes are violent movements of the fœtus, exciting contractions, and the tugging of the child on a cord absolutely short, or rendered short relatively by looping around the neck, trunk, or extremities of the child. Finally, cases do occur which do not have any discoverable cause.

Symptoms.—I. Visible variety. In very mild cases we have but a small amount of hemorrhage, with or without pain, depending upon the area from which blood escapes, a slight separation at the placental edge giving rise to little disturbance. In severer cases we usually find considerable bleeding with sharp pain, referred to the placental site, and can sometimes detect a certain amount of elevation over the seat of hemorrhage, due to the uplifting of the uterine wall at that point, this very distention causing pain. Some patients show marked symptoms from a comparatively small blood loss, while others feel the loss of large amounts very little. In the severe cases all the symptoms are usually well marked, pain being a prominent feature, more or less shock from extensive laceration being present, and large quantities of bright blood escaping. In some cases the flow is so profuse as to be mistaken for the hemorrhage occurring in placenta prævia. Associated with this profuse hemorrhage we find marked constitutional symptoms, extreme pallor, the skin cool and bathed in perspiration, pulse rapid and feeble, sighing respiration, air hunger, great thirst, restlessness, anxious facial expression, dull pain in the back, dilated pupils, and blanched mucous membranes. Such a clinical picture once seen, cannot be forgotten.

II. Concealed variety. As we have seen, there are some very mild cases which give no clinical symptoms. But the typical severe concealed form is the very gravest perhaps with which we must deal, for so much hemorrhage may have occurred before the true condition of affairs is discovered that the woman's life will be in jeopardy even before treatment is instituted. The symptoms in such cases in their appearance will depend on the rapidity with which hemorrhage and separation take place. If the loss of blood within the uterine cavity is slowly and steadily increasing in amount, we find the gradual development of signs which in some cases appear within perhaps a very few minutes. Some pain will be felt, the uterus will gradually but none the less surely become enlarged, and from the distention, pain will become more or less general, the uterus being also tender to touch. Fœtal movements and heart sounds will cease and palpation become impossible, on account of tenderness. After a time blood may appear externally, but this is merely from overflow, so to speak. If no help be given, the patient will die from shock and acute anæmia. When a large amount of blood suddenly escapes, we have shock as a marked feature, with all the signs of hemorrhage enumerated above. Pain, shock, and signs of hemorrhage then, will characterize these severe cases, and yet perhaps no blood be actually seen.

Diagnosis and Differential Diagnosis.—From the symptoms just mentioned, the true condition of affairs can usually be easily made out. A vaginal examination will tell us absolutely that we are not dealing with placenta prævia, and whereas pain is a prominent symptom in accidental hemorrhage we do not find it as a rule in placenta prævia. Again, the concealed variety is radically different, in that hemorrhage occurs within the uterus, and that of placenta prævia external to it. There is one other condition with which concealed hemorrhage might be confounded, namely, rupture of the uterus. This, however, occurs as a rule late in the labor, after the membranes have ruptured, is not accompanied by enlargement of the uterus, and if the rent is large enough for the child to escape, the presenting part slips away from the brim and the regular contour of the uterus is lost. The child may be felt through the abdominal wall, but great care must be exercised with regard to this, as some uterine walls are so thin as to enable one to make out the small parts of the child with almost startling distinctness.

Prognosis.—A number of cases with proper treatment may go to full term, but, as a rule, for various reasons, already mentioned, labor comes on within a short time after the first hemorrhage. In the mild cases the prognosis for the mother is very good, while that for the child naturally depends somewhat upon the period of gestation at which hemorrhage occurs. But at full term the mortality for the child ought not to exceed fifteen per cent., while in premature labor it is much higher. In the severe forms the prognosis is very grave, the mortality according to Storer's figures being 46.7 per cent. for the mothers and 94 per cent. for the children. Thus we see that in the severe cases practically all of the children die and about one-half of the mothers.

Treatment.—I. Of the very mild cases, with slight amount of hemorrhage and little if any pain. The patient should be put to bed in a quiet room, on light diet, and kept as still as possible. A small dose of morphine acts well in securing perfect rest. No tampon should be used, but a clean pad can be placed over the vulva in order to exclude as far as possible infection, and to absorb the small amount of blood. The tampon, if used, would obscure our observation in regard to the progress of the case. Careful note must be made from time to time in regard to the size of the uterus, fœtal heart, pulse, etc., in order to guard against possible internal bleeding. Little if any harm can result from the careful observation of such a case, and if further separation does not occur the life of the child may be saved. If bleeding continues, or if the blood loss is considerable when the case is first seen, more active measures must be resorted to. In checking uterine hemorrhage we aim to secure contraction, and this can as a rule be speedily brought about by a rupture of the membranes. This treatment in the vast majority of cases will be sufficient to stop all further trouble, and the uterus will, after the amniotic fluid has drained away, generally contract about the child, and in that way close the uterine sinuses. We can, and should, I think, assist nature in such cases, by frequent administration of moderate doses of strychnine and quinine. Then from time to time, if slight bleeding continues, the cervix should be stretched to some extent, using, however, but little force. Should the measures spoken of prove ineffectual, delivery must be completed in as short a time as is practicable, consistent with the welfare of both mother and child. Manual dilatation should be used, and this followed by the application of forceps, or the operation of version.

II. In the severe form, visible or concealed, the rupture of the membranes should be the first treatment used. If active bleeding is going on, steps must be taken at once toward emptying the uterus. Manual dilatation of the cervix must be performed rapidly, as the urgency of the case requires, and the child delivered by forceps, version, or craniotomy, careful attention being constantly paid to the general condition. In such cases delay is very dangerous, and only quick intelligent treatment will give any hope of success. If, on the other hand, hemorrhage has apparently ceased, or the patient be in very poor general condition, it is better to empty the uterus slowly, thus avoiding the shock of a rapid extraction, and at the same time pay all possible attention toward the improvement of the state of anæmia and shock. By so doing we certainly increase the chances of success, by

adding, at least, no other element of injury and consequent shock. Fluid must be supplied in large amounts by mouth and rectum, and if necessary by infusion. Stimulation must be very free, and too much stress cannot be laid on the free use of hot saline stimulating enemata. It is remarkable to watch the improvement in the heart action after the exhibition of one or more hot salines. The system needs fluid urgently, thirst will be greatly relieved, the heat and stimulants both act well on the heart. During the past year there have been four interesting cases of accidental hemorrhage at the Sloane Hospital, and a brief summary of these will, I am sure, reward your careful attention.

Case I.—M. McK——, twenty-four years of age, married, primipara, eight months pregnant, admitted to the hospital, August 26, 1896, at 11:45 A.M., with the following history: The woman had been in excellent health until forty-five minutes before admission, when she felt some pain and began to bleed profusely. After some delay an ambulance was summoned, and the patient carried quickly to the hospital. From her own account about one pint of blood was lost at home. On admission the woman looked as if she had already lost a very large amount of blood; there were marked pallor, restlessness, pulse soft though slow, and anæmic mucous membranes. The uterus was distended and very tense, palpation impossible, fœtal heart not heard. The vagina was filled with bright red blood and recent clots; the cervix barely admitted one finger. Absolutely nothing could be felt with the examining finger in the cervix but recent clots. There was no placenta near the internal os. As hemorrhage was profuse, the woman was carried at once to the operating-room, where she was quickly prepared for operation. So grave was her condition that preparation was made for intravenous infusion in case of need. The indication for immediate delivery was clear, hence the cervix was quickly dilated with the hand in order to perform version. The cervix was immature and did not yield readily, but bleeding was so profuse, and pulse becoming so rapid and feeble, that the hand in the form of a cone was quickly pushed up into the uterus. The entire lower half of the uterus was filled with freshly clotted blood and the fœtus in its membranes had been crowded up into the fundus. The placenta was attached to the right side of the body and fundus uteri, and a large loose flap was felt, from the detachment of which the profuse hemorrhage took place. The child was lying in transverse position, head to the left, back above. The sac was immediately ruptured, the right foot seized and brought down. As I delivered the foot, clots and fluid blood came away, to the amount of about one quart. The pulse was now so feeble that infusion was done at once in the left arm by Dr. La Fétra, the senior assistant. The pulse improved after this, with the aid of hypodermic injections of whiskey and strychnine. Meanwhile the child was being slowly and carefully extracted, and was born at 12:39 P.M., within one hour after admission. The child was dead, and apparently of eight months' gestation. The placenta was expressed at once, and a vaginal douche checked further hemorrhage, the uterus contracting nicely. The pulse was now fair in character; free stimulation was resorted to by rectum, mouth, and hypodermics, hot bottles were applied, the foot of the table was elevated, and an injection of morphine was given. Between 1 and 2:30 P.M. she seemed to be doing fairly well, but at that time she vomited a large amount of fluid, and the pulse became rapid and feeble again. The uterus was well contracted; no further bleeding had occurred. At 2:50 P.M. another intravenous infusion was given, with free stimulation subcutaneously, but the pulse became steadily worse and the woman died at 3 P.M. The autopsy showed marked signs of profound anæmia, heart extremely flabby, bloody serum in pleural, pericardial, and peritoneal cavities, lungs œdematous, a laceration through the right side of the cervix, and extending about one-half inch above the internal os, and an infiltration of the right broad ligament with a small amount of blood. The woman lost in all, in the hospital and at home, probably sixty ounces of blood, and the undoubted cause of death was acute anæmia from accidental hemorrhage, laceration of the cervix and consequent shock no doubt contributing.

Case II.—M. McG——, forty-three years of age, married, XIV gravida, at full term. All previous labors easy, with exception of last two, in which instruments were used. The patient came into the hospital November 28, 1896, at 12:10 P.M., with the following history: No trouble had occurred at any time during pregnancy until 6 A.M. of the day of admission. At this time while lying in bed, a gush of bright blood appeared, and bleeding continued all the morning until a tampon was applied at 11 A.M. After this, very little blood escaped, and the tampon was kept in place until the patient was ready for operation. Pain began at 6 A.M. also, and labor probably commenced at that time. No fœtal movements had been felt since the preceding midnight. The woman must have lost a great deal of blood, from the statement of her physician, before he applied the tampon. On admission, the patient was found to be a large, stout, anæmic-looking woman evidently suffering from acute anæmia. When the tampon was removed, the cervix was found to be soft, admitting three fingers; the membranes were bulging to moderate extent, between as well as during pains. Moderate bleeding commenced and continued after removal of the tampon. The abdominal wall was very thick, and palpation difficult. The vertex presented at the brim, in R. O. P. position; the fœtal heart could not be heard. Her pulse was 110, very soft; skin cool and covered with perspiration; face very pallid, with anxious expression. As no placenta could be felt near the internal os, the diagnosis of accidental hemorrhage was clear. Dr. McLane, who was called to the hospital to see the case, advised immediate rupture of the membranes, and after he had done so, removing several quarts of liquor amnii, found that the head acted as a sort of "ball valve," in preventing escape of blood. As the necessity for immediate delivery was apparent, Dr. McLane dilated the cervix with the hand sufficiently to apply the forceps. Attempts to deliver by forceps were unsuccessful, and, as the child was no doubt dead and bleeding continued, craniotomy was advised. With the basiotribe of Tarnier this was done by the writer, the rest of the delivery being comparatively easy, with the exception of the shoulders, which were large. The placenta was lying in the vagina, and withdrawn by the hand. The amount of hemorrhage during the entire delivery was forty ounces, estimated and weighed. This amount in addition to that lost at home was so large that the woman's general condition was now very poor, in spite of free stimulation during delivery. But after elevation of the foot of the table and further stimulation by enemata and hypodermic needle, the condition improved to such an extent that infusion was not performed. It may be interesting to note that the patient received nine hot saline enemata, each of one pint, during the following twelve hours, almost all being retained. Notwithstanding the immense loss of blood, the patient recovered nicely, and left the hospital at the end of five weeks in good condition, considering the anæmia, which will take months to cure. A more typical case of severe visible hemorrhage could not be given.

Case III.—The next case I am able to present

through the kindness of Dr. E. A. Tucker, in whose service the case occurred and who had entire charge of the treatment. M. M——, thirty-eight years of age, married, VIIIgravida, pregnant about seven months, came into the hospital December 20, 1896, at 3:15 P.M., giving the following history: Her health had been apparently good until midnight of the preceding day, when she began to suffer from a great deal of pain across the upper part of the abdomen. No fœtal movements had been felt for several days previous. A physician was called in, and an injection of morphine given. Slight external hemorrhage had appeared, but labor had not yet begun, and the fundus was about two fingers above the navel. A very small quantity of urine was withdrawn by catheter. During the rest of the night and day, up to the time of admission, very little blood escaped externally, but her condition grew steadily worse, and the fundus crept up slowly until it had reached at the time of admission (or within twelve hours) a point about one and a half fingers below the ensiform cartilage and underlying the ribs on either side. On admission the uterus was found large enough for full-term gestation, with very tense walls, and the abdomen also very tender to touch. Palpation was impossible and the fœtal heart could not be heard. The cervix admitted two fingers; membranes were tense; labor had not yet begun, and very slight bleeding was taking place. The patient was very restless and markedly anæmic; the mucous membranes were dry and pale. Dull aching lumbar pain and great thirst were complained of; the pulse was rapid and irregular, though still of fair force. The patient vomited several times after admission; the temperature was subnormal, and from all appearances the case was one of urgent concealed accidental hemorrhage. The woman was perfectly conscious and answered questions well. Preparations were made at once for immediate operation. The catheter withdrew four drachms of bloody urine, which under the microscope revealed no casts. In order to get as much fluid as possible into the system, a quart of hot saline was given by rectum, and retained. The first step taken was the rupture of the membranes, allowing about ten ounces of fluid to escape. As no active hemorrhage was going on, the cervix was now left to soften, as it was very rigid and unyielding. Another saline enema was given and retained. In order to hasten delivery, at the end of an hour and a half the cervix was slowly dilated so as to admit four fingers. A loop of cord, cold and pulseless, had come down during the interval of waiting, but no attention was paid to it. The vertex in L. O. A. position was at the brim, and as the child was dead Dr. Tucker decided to perforate and then allow the head to mould into, and, if it would, through the cervix. The perforator of the Tarnier instrument was therefore passed into the head at 6 P.M. and the brain broken up, thus allowing the head to collapse to a certain extent. Another saline was then given, whiskey and cracked ice were given by the mouth, and hot bottles were placed around the body. As very little progress had been made at the end of one hour, it was decided to deliver with the basiotribe. This was done and the child was born at 7:25 P.M., the delivery of the trunk being made slowly in order to guard against rapid evacuation of the uterus. No gush of blood followed, and the pulse of the patient came up well with a hypodermic injection of whiskey. During the third stage, as no bleeding occurred, the uterus was simply held, no pressure being exerted. With the placenta came away a few small clots of dark blood. Further pressure brought away more dark clots, until finally, when the uterus was empty, twenty-nine ounces of blood had been removed, this being the amount of concealed hemorrhage. An acetic-acid uterine douche was then given and no bleeding whatever took place. The patient seemed now to be in fair general condition, and the prognosis appeared to be hopeful. Under routine treatment she recovered from the hemorrhage and delivery, but the kidneys unfortunately refused to act, and in spite of all treatment the woman died seventy-two hours later, having passed but one and a half drachms of urine by catheter during this entire time. This urine showed a high percentage of albumin, granular casts, pus, and epithelium. Full autopsy was refused, but the kidneys showed chronic nephritis and an intense acute exudative nephritis, which were the cause of death. The old nephritis acted undoubtedly as a strong predisposing cause to hemorrhage. Her death cannot be attributed to the accidental hemorrhage in itself, but to the complicating renal condition. Curiously, this same woman had been treated by Dr. Myers, a member of this society, four years before, for the same trouble. She was at that time seven months pregnant, suffered from severe pain, hemorrhage, and almost died before the child was delivered. The placenta showed an old clot, almost entirely covering the maternal surface. It may be noted here that the placenta from the last delivery showed traces of old hemorrhage, in the form of a number of small old clots. The patient was sure that no bleeding had ever taken place during this pregnancy before the present time.

Case IV.—The last case which I shall mention is one of such rarity that great interest attaches to it. F. J——, twenty-seven years of age, negress, married, primipara, came into the hospital December 21, 1896, at 5:45 P.M. with the following history in brief: During the week preceding admission the patient had characteristic symptoms of acute nephritis. On the evening before admission she had complained of sharp abdominal pains, and vomited several times. In the early morning of the day of admission she had an eclamptic seizure, remained unconscious during the rest of the day, and had a number of other seizures. On admission, the patient was moribund, pulse extremely rapid and feeble, conjunctival reflex absent; she was in deep coma. Temperature was normal; respirations, 44 to the minute. The uterus was at eight months' mark, distended, and had very tense walls; palpation impossible. No fœtal heart could be heard. A small amount of fluid blood was found in the vagina; the cervix was of medium length, moderately soft, and admitted one finger with ease. Labor had probably begun some hours before. The vertex presented at the brim, position R. O. A. Diagnosis was clear of eclampsia, with accidental hemorrhage, no placenta having been felt. The woman was carried at once to the operating-room; the membranes were ruptured, about eight ounces of fluid coming away, and preparation was made for operation. In a very short time, however, the patient was seen to be dying, and in spite of stimulation the pulse became imperceptible and the woman died. During the last few minutes of life, preparation was completed for Cæsarean section, and when the heart stopped the writer made a long median incision through the abdominal and uterine walls, and the child was quickly lifted out. The death of the fœtus had occurred, however, some time before, as maceration had already commenced in many parts. Immediately after the child was removed, the fœtal surface of the placenta bulged up into the wound, showing pressure from behind. The entire uterus was removed from the body, and the following interesting condition of affairs discovered: Behind the placenta and almost completely separating it from the uterine wall was a large thick clot of dark blood, weighing from six to eight ounces. Other clots had dissected off the chorion from the uterine wall below and to the left of the placenta, the edge of the lowest clot almost reaching the internal os. Altogether there were probably ten to twelve ounces of concealed hemorrhage.

The patient had not bled at home, and the amount of external hemorrhage was exceedingly small. The urine was almost solid on boiling, and showed many granular casts, while the kidneys on section showed intense congestion. It is reasonable to suppose that during an eclamptic seizure, or possibly before, on account of the acute nephritis, separation had taken place, which resulted in the concealed hemorrhage. Eclampsia was the undoubted cause of death, but the case is reported for the very interesting condition present, one in fact which is extremely rare, showing, as the uterus did, an extensive concealed hemorrhage, *in situ*, very slight external evidence having been present.

THE USE OF THE PERMANENT-EXTENSION CORSET AND FRAENKEL'S EXERCISE IN TREATMENT OF LOCOMOTOR ATAXIA.

By LEONARD WEBER, M.D.,

NEW YORK.

By a short passage in the MEDICAL RECORD of January 23d, that the value of Motschukowsky's treatment of tabes by temporary suspension will not be appreciated to its full extent by the profession at large until permanent suspension by means of the extension corset has replaced temporary suspension, I am reminded of the subject of mechanical treatment of tabes as described by me in a paper, "The Present State of Treatment of Chronic Diseases of the Spinal Cord, Especially of Tabes and Neurasthenia," read before the New York Neurological Society, April 5, 1892, and published in the MEDICAL RECORD, May 28, 1892.

I stated therein that in 1889 a well-known clinician —Professor Jürgensen— had endorsed the orthopædist Hessing's treatment of locomotor ataxia by permanent-extension corset, and said, in a letter published in a German medical journal, that he had known it to be successful in one or more well-marked cases. The corset was to act after the manner of Motschukowsky's suspension, but in a permanent way and with less danger and severity. While abroad in the spring of 1890 I saw Mr., now Dr., Hessing's famous orthopædic institute at Göggingen, a suburb of Augsburg, in Bavaria. I found an immense establishment, consisting of many buildings situated in a small park, with theatre and concert hall for the entertainment of the numerous patients, an elegant restaurant, etc.—in fact, a special plant, the like of which does not exist anywhere else, I believe. Mr. Hessing, proprietor and director of all, received me kindly, and allowed me to examine and converse with such tabetic patients as were then under treatment by the applications of the permanent-extension corset. Mr. Hessing considered this mode of treatment to have been original with him, as much so as his way of putting up a recently fractured lower limb, after perfect reduction, in a protective apparatus so well fitted and adapted that the patient was enabled to walk about in a few days with apparatus on and have his fractured limb get well in much shorter time than in the old way. He was then just about preparing a paper on the latter subject, to be read before the annual congress of German surgeons, with demonstrations of cases.

Hessing's views at that time with regard to the pathology of locomotor ataxia were peculiar. His idea was that most cases started with disease of the osseous and ligamentous structure of the spine, affecting the meninges and cord later on, in some cases perhaps simultaneously. Upon this theory it was but natural for the eminent orthopædist to hope that, by the proper application of a supporting and extending corset, to be worn night and day if possible, we might put our patients in the best possible way of relief and cure. His patients submitted as well as they might to the discomforts in wearing the apparatus. Many of them complained much of pain and numbness in hands and fingers, with occasional œdematous swelling of the same, caused by the pressure of side supports against the armpits.

Hessing said to me: "I have had thus far about sixty cases in all stages under treatment, and am well pleased with the results as to local and general improvement. But as to curing these unfortunate people, that will be very hard to do by any mode of treatment, for many of them have diseased brains also, and I find it next to impossible to carry out my plan of treatment with them, as I should like to."

These remarks show that Hessing was far from satisfied with his final results, and my suspicions in this direction were also confirmed by the statement of one of the patients present, who said that he had been under the doctor's care pretty steadily for two years, but had seen no tabic patient cured, and himself, though improved as to general nutrition and some of his pains and paræsthesias, was pretty nearly as ataxic as when he first came. After all I had seen and heard at Hessing's place, I did not feel encouraged to try this mode of treatment for ataxia, nor urge its adoption with those of my friends who have larger opportunities than myself to try it on an extensive scale.

If better and less cumbersome permanent-extension corsets than those I saw in use at Hessing's in 1890 are now constructed and used with advantage, I am very glad to know it.

With regard to Dr. Fraenkel's exercise therapy, I have had some positive experience in improving and partly overcoming the ataxia of tabes, as well as the motory weakness of neurasthenia gravis. It is nearly six years since Dr. Fraenkel, in Heiden, near Korschack, Switzerland, published a paper upon the exercise treatment of tabic ataxia. In May, 1896, he read a paper on this subject before the Berlin Clinical Society, published in the *Deutsche medicinische Wochenschrift*, December 17, 1896, with cases treated more or less successfully; and he is now preparing an extensive monograph, in which he promises to describe the exact technique of the exercises.

In the *Post-Graduate Journal*, vol. ii., No. 7, Dr. C. L. Dana says that he has seen most satisfactory results from this treatment in correcting ataxia, and describes the exercises as he orders them for his patients, more or less strictly after the formulas prescribed by Drs. Fraenkel (1890) and Hirschberg (1893).

Reserving a detailed account of my cases treated in the manner aforesaid for another time, it is but proper to state here that the exercises are not difficult to learn, and that the patients, soon noticing some improvement in the power of co-ordinately using their motory impulses, readily persist in the daily practices.

25 WEST FORTY-SIXTH STREET.

Contraindications of Altitude in Phthisical Cases. —1. Phthisis with double cavities. 2. Fibroid phthisis and all other conditions in which the healthy pulmonary area hardly suffices for respiratory purposes at sea level. 3. Catarrhal and laryngeal phthisis. 4. NEURASTHENIA AND ITS RELATION TO OTHER DISEASES.

By A. D. ROCKWELL, M.D.,

NEW YORK.

In that remarkable work, "The Art of Prolonging Life," written more than one hundred years ago, Hufeland speaks of imaginary conditions and morbid fears peculiar to hypochondriasis, which are brought on by brooding, reading works on medicine, excesses, etc. He evidently had seen cases of neurasthenia, although unconscious of their significance. Indeed, Arndt asserts that neurasthenia has been known for thousands of years. He, too, was unconscious of its significance, and both regard the fear and dread thus occasioned as imaginary and would disssipate them by an effort of the will, not recognizing the fact that morbid fears are in the main dependent upon some vice of constitution, either autoinfection, due to malassimilation and imperfect oxidation of food products, or to mental and physical stress and strain that result in veritable cell exhaustion.

The will can do much, but it cannot do all; and in neurasthenic conditions as we commonly find them, the unaided will is a very unimportant factor. Impairment of will, indeed, as has been well said, "is the keynote to the psychic state in neurasthenia." One cannot use what one has not, and the will power that emanates from an exhausted brain is so insignificant that the slightest obstacle becomes insurmountable.

To tell a man with profound neurasthenic symptoms that he is all right, that there is really little the matter with him, and that all he needs is to "brace up" and not give way to unnecessary and unreal emotions and sensations, is very much like attempting to persuade a man on his way to the gallows that there is nothing real or disturbing about his situation. I do not know to what extent the general practitioner sees and recognizes these cases, but experience teaches me that he sometimes inflicts injury that is neither light nor easily effaced, by giving no heed to or misinterpreting a tale of woe because he fails to detect objective symptoms of disease. Gowers, in his masterly work on nervous diseases, devotes fifteen hundred pages to the elucidation of the symptoms, morbid anatomy, and pathology of a host of structural and organic diseases, for which little or nothing can be done in the way of treatment. He devotes less than a page to a condition that occasions far more misery and paralysis of utility than many a hopelessly incurable organic lesion, and for which very much can be done in the way of successful treatment. Perhaps no greater misconception of the true state of mind and body of a typical neurasthenic can be found than when he says: "To describe the symptoms and treatment of all that may be collected under the name neurasthenia would be to repeat that which has been stated already in its proper place [in his book], especially in the sections on neuralgia, headache, cephalic sensations, hysteria, and hypochondriasis."

These conditions, one and all, are simply shifting symptoms of the neurasthenic state, and in its treatment they deserve no more consideration than the multifarious symptoms that are associated with any grave constitutional disturbance.

Since the term neurasthenia with its peculiar congeries of symptoms had its origin in this country through the labors of Beard, and has even been called the American disease, it is with no little satisfaction that those of us who have earnestly contended that it should hold a distinct position among diseases note that many of the keenest observers in neurology, both here and abroad, in Germany and France, are fully alive to its importance and reality. Bouveret believes that neurasthenia should be attributed to a disturbance of the nutrition of the nervous elements, to an impoverishment of the nervous force, and especially to a chronic enfeeblement of the superior nervous centres which regulate the activity of the inferior centres. The exaggerated action of the brain in the sphere of the intellectual faculties is the most common and best-established cause of nervous prostration. It is common also from the abuse of stimulants, from excessive muscular exercise, and from sexual excesses.

Benedict considers neurasthenia as a psychical condition excited by psychical emotion and intellectual overwork; claims that psychical treatment is equally important, and that the moral cure has been of late neglected, although he is distinctly sceptical as to the cure of all ills by suggestive treatment. The important question is whether to permit the neurasthenic to work or to demand absolute rest. Strictly absolute rest, however, increases the affection, and the patient should always be led to occupy himself in a suitable manner. He thinks isolation or removal from one's family or surroundings is often essential. He claims that if the Americans would learn from the Germans how to amuse themselves instead of yawning on holidays, the danger of neurasthenia would be diminished. Whoever has not learned how to play and jest, easily succumbs to mental work. He lays especial stress upon electricity; and for drugs, upon iron and arsenic.

Blocq considers neurasthenia as a neurosis, which in every case has its seat in the brain.

The list of other foreign writers whose words are based on the authority of long and tried experience, and who are fully alive to the reality and importance of this disease which has ruined so many lives, include Champagnac, who does not accept the nervous theory of Beard, but believes neurasthenia to be closely related to alteration in the digestive tract; Fournier, who is surprised that syphilis has been so little considered as a cause of neurasthenia; Savage, of London, who regards neurasthenia as a disturbance of the peripheral nervous system analogous to general paralysis; Vigouroux, of Paris, who believes the important etiological factor to be overactivity of the organic centres and the diminution of nutritive metabolism; Lowenfeld, who endeavors to reconcile neurasthenia with the uric-acid diathesis; Grasset, who attributes all neurasthenias to overwork of every kind; Joseph, of Landeck, who in studying the etiology of neurasthenia admits that it is generally caused by whatever enfeebles the human organization by prolonged action; and Kowalewsky, who considers that when the nervous system does an excessive amount of work sufficient nutritive material is not brought to the centres of activity, and, furthermore, by the continuance of their activity the waste products are not carried away as speedily as they should be. This leads on the one hand to malnutrition, and on the other to intoxication from the waste products. In certain conditions, however, he holds to Arndt's theory that many of the cell elements in the nervous system of some patients show a defective development. In such cases neurasthenia is more clearly a congenital condition, and is, of course, much more easily developed. Bordarie advances a similar theory, basing the condition upon a vasomotor disturbance and excitation of the vasomotor centres, leading to a diminished nutrition and a consecutive intoxication; while Dujardin-Beaumetz and others discuss the frequency of dilatation of the stomach in neurasthenia, and advise local treatment as in dilatation from other causes.

These views comprise but a small part of the literature of neurasthenia, and I quote them to show that, however much men may differ in the minor details of

its nature, its causation, or its treatment, it would seem useless to contend, as Gowers has done, that neurasthenia cannot be regarded as a distinct disease, or that the symptoms of every so-called neurasthenic patient are sufficiently definite in character to bring the case into some special category of other well-known diseases. For purposes of rational treatment, however, it does become necessary to differentiate between true neurasthenia and pseudo-neurasthenia, a condition quite different and one which some of the authorities just quoted evidently confounded with the classical disease. My meaning cannot, perhaps, be better conveyed than by reiterating what I have said in another place: "Neurasthenia is now almost a household word, and equally with the term malaria affords to the profession a convenient refuge when perplexed at the recital of a multitude of symptoms seemingly without logical connection or adequate cause. The diagnosis of neurasthenia, moreover, is often as satisfactory to the patient as it is easy to the physician, and by no means helps to reduce the number who have been duly certified to as neurasthenic, and who ever after, with an air too conscious to be concealed, allude to themselves as the victims of nervous exhaustion. The doctrine to be taught and strongly enforced is that many of these patients are not neurasthenic, and under hardly any conceivable circumstances could they become neurasthenic. They do not belong to the type out of which neurasthenia is born, either mentally or physically. Many of them are unintellectual, phlegmatic, and intolerably indolent, and are pleased at a diagnosis which touches the nerves rather than the stomach, bowels, and liver. The treatment needed is quite different from that of the true neurasthenic. These patients are lithæmic, not neurasthenic: the nervous system is strong enough, and would give no trouble were it not poisoned by the abnormal products of digestion, that enter the blood and circulate through every tissue of the body."

It is this lithæmic condition, so often mistaken for neurasthenia, of which Haig has been one of the later exponents. He dwells upon the importance of the retention of uric acid in the system in the causation of nervous disorders. These disorders, however, are in no sense neurasthenia. They consist, as Murchison had pointed out before him, of headache, vertigo, convulsions, depression, irritability, sleeplessness, pains and neuralgia, migraine and paralysis. According to his idea, those who indulge freely in meat and wine, and take of any food more than the system can oxidize, have a tendency to store up uric acid in the system.

Leubucher has studied many cases of nervous diseases, melancholia, and mania especially, and it was surprising how in most of these cases an examination of the secretions showed greatly increased acidity. Now it is an extremely easy matter, as a rule, to diagnosticate a functional disease of the nervous stystem from an organic disease; but it is not always so simple a matter to diagnosticate a neurotic condition, dependent upon retained uric acid or faulty metabolism in any way, from a condition of true neurasthenia. The presence of uric acid does not determine the difference, since uric acid is not infrequently found in the urine of neurasthenics, while the worst lithæmic may at times give no evidence of its presence. Differential points of importance refer to the mental phenomena. Mental depression and a profound sense of misery belong to both types, but with very different manifestations. The neurasthenic, however much he may suffer in mind, and however much he may worry in regard to his own condition and the affairs of the world generally, has no such irritable, ungovernable temper as the lithæmic.

In neurasthenia, the nutrition of the nerve cells is believed to be at fault. They are in a condition of pathologic fatigue, brought about by voluntary or involuntary stimulation of brain activity, frequently repeated to the verge of exhaustion, until the recuperative power fails to bring back the nervous tone to its normal level.

Suffering in this way, the demeanor of the neurasthenic is, as a rule, quiet and suppressed. He is timid and retiring, and one seldom sees in him the touchy mood of the lithæmic, whose brain is actually poisoned by the imperfectly transformed products of digestion. In lithæmia the tongue is generally coated, and where you will find one neurasthenic with cold hands and feet, you will find a dozen lithæmics bitterly complaining of this condition. The nitrogenized wastes circulating in the blood cause by their irritation tonic spasm of the arterioles and local anæmia.

No two conditions of disease, with such similar symptoms in many ways, demand such widely different methods of treatment.

Haig would remove the uric acid by salicylates and acids, and prevent the formation of more uric acid by an appropriate diet. The necessity is not for rest, or quiet, or soothing draughts, but for mental and physical activity, and sometimes actual starvation.

The neurasthenic, on the contrary, frequently needs more food and of the best quality—repletion rather than depletion. He may need absolute rest and quiet, or at least an entire change in the character of his work, and whatever methods tend to improve nutrition must be persistently attempted.

I have had cases in which absolute rest in bed, as advocated by Weir Mitchell, has been of service; but in the great majority of cases the monotony of complete rest acts as an irritant rather than as a tonic sedative. Activity along some line, tempered to the characteristics and necessities of the patient, is far more potent for good than absolute idleness, while a judicious use of a combination of the three bromides, with some one of the zinc preparations and cannabis indica, is perhaps the most efficient form of internal medication. These drugs are not tissue builders, nor are they tonics in the ordinary acceptation of the term, but they temporarily curb the erratic and unstable nervous system, and enable it to receive with better effect those methods of electric application which experience has proven to be so valuable as an aid to animal nutrition.

In regard to the use of electricity in neurasthenia, there is much to be said, and if time permitted I should be glad to consider at length the *rationale* of its effects.

The fundamental principle underlying all the reconstructive and curative effects of electrization is its power over nutrition. The neurasthenic patient looks so well, is frequently so plump and healthful in appearance, that we are accustomed to say that he is well nourished, that his nutrition is good. This, however, cannot be. The morbid fears, the strange and persistent sensory symptoms, the vacillation, the feeble powers of endurance—all point to deficient nutritive activity; and whether we regard the pathologic change in the cell to be due to fatigue, to inanition, or to direct toxic influence, the processes of metabolism are undoubtedly defective, both in constructive and destructive power. Few facts are more clearly established than the influence of electricity, first upon the metabolic function of the body, and secondarily over nutrition. Through physiologic experiment and chemical analysis, we know of its effects upon metabolism; through clinical experience and observation, upon nutrition. Every manifestation of electricity possesses this power in greater or less degree, and it is most unwise, it seems to me, to select and dwell

upon any one form as the special medium through which nutritive effects are best obtained.

It is through the mechanic, chemic, and physiologic powers of electricity that we influence nutrition, and that form and method of treatment which in the most thorough manner combines these effects, as indicated in individual cases, will prove the most effective.

The relation of the morbid fears of neurasthenia to other diseases, and especially to epilepsy, is of great interest. Many a neurasthenic will appear to be on the verge of an epileptic attack, and it is not uncommon for them to think they are about to have it; but, as a rule, their very disease saves them from it. Nevertheless, although the two diseases, epilepsy and neurasthenia, evidently belong to different orders of constitution, yet in a number of cases that have come under my observation I have found an epileptic attack and morbid fears to be convertible terms. I well remember the case which first called my attention strongly to this fact. A young man, aged twenty-four, came to me, some years ago, complaining of symptoms that had become chronic, typical of true neurasthenia. His morbid fears took the form of monophobia—fear of being alone. He seemed to be afraid of nothing else, but rather than sleep alone or remain in a room alone he would sit up all night or walk the streets for hours. He had never suffered from any form of convulsive seizure, but shortly after he came under my observation he was seized with an epileptic paroxysm of considerable severity, which was repeated every few weeks for more than six months; but the morbid fears left him at once and completely. When the epileptic attacks began to decrease in severity, the morbid fears began to return, mildly at first, but increasing in severity as the epileptic attacks subsided. Evidently the same pathological condition, whatever that condition was, that caused the morbid fears was the cause also of the epileptic seizures. The practical point that I desire to make in regard to this occasional combination or alternation of two very distressing symptoms relates to the treatment. The epilepsy associated with neurasthenia is a different and less grievous affair than when due to reflex irritation from central traumatic causes, to organic brain disease, or the ordinary so-called idiopathic variety. In most cases of epilepsy from these causes the "fits" act as safety valves, the secondary effects of which are a general mental and physical uplift; but in cases of what might be termed neurasthenic epilepsy the attacks are not followed by the same measure of relief. The prognosis, however, in neurasthenic epilepsy is far better than in epilepsy unassociated with the neurasthenic condition.

In the latter case the bromides are unmistakably beneficial, and sometimes curative, and are not, as a rule, distinctly harmful; but in the epilepsy that displaces the morbid fears of neurasthenia bromides are in my experience less serviceable and more depressant.

For this reason, in those cases of neurasthenic epilepsy that come under my observation I am much more careful in the use of the bromides, and, indeed, treat the cases constitutionally, very much as neurasthenia itself is treated, by those methods that tend to aid cellular nutrition, and especially by central galvanization —than which there is no more efficient method in the treatment of chronic functional derangement of the central nervous system.

My experience does not teach me that syphilis bears any very important relation to neurasthenia, as suggested by Fournier. It may occasionally complicate it, but the great majority of my own cases had never contracted the disease. It is unquestionably true that nervous exhaustion saves from disease. Those afflicted with it are, for example, less liable to inflammatory conditions. Their gonorrhœal attacks are lighter, and I have seen enough of syphilitic attacks in neurasthenics to incline to the belief that both local and constitutional effects are less severe than in the perfectly well.

Organic diseases of the brain and spinal cord or of the peripheral nerves are very insignificantly related to neurasthenia in any real sense.

Very few neurasthenics develop structural disease, and it is rare to see the latter associated with the symptoms of true neurasthenia; but the tendency to mistake one for the other, although not so prevalent as formerly, is by no means rare.

Deficient mental control, sensory symptoms, and local fibrillary contractions are the symptoms which, according to my experience, cause the greatest alarm to the intelligent patient. If the patient be a physician or one who has made himself familiar with the symptoms of central organic disease, the deficient mental control suggests to him insanity, the sensory symptoms locomotor ataxia, and the fibrillary contractions progressive muscular atrophy. The importance of a correct diagnosis cannot be overestimated. The gravest consequences may follow such mistakes, and it would seem that no adequate excuse can be offered for them. To mistake an organic for a functional condition is not, as a rule, so serious a matter. It is, indeed, sometimes desirable to keep for a time the worst from a patient; but to tell one afflicted only functionally that his disease is organic and incurable is a most serious matter. It takes away hope, shatters the *morale*, and materially lessens the chance of ultimate recovery.

Infiltration Anæsthesia.—The fluid consists of a very dilute solution of cocaine and morphine, with a small portion of chloride of sodium. The needle of the syringe is introduced at a point in the area which it is desired to render anæsthetic, and keeping it parallel with the surface is pushed on until the eye is hidden. A few drops of the fluid are then injected, and a wheal is instantly produced which is anæsthetic. The needle point is then withdrawn and reinserted within the wheal in the line of the proposed incision, and the process continued until the whole area that it is desired to anæsthetize has been rendered insensitive. If the operation be a simple skin incision, as the opening of an abscess, this is all that is necessary; but if a small tumor is to be removed, it will be necessary to infiltrate the tissues under the skin after this has been incised. In minor operations it is very successful. Its safety is beyond question.—FIFE.

THE ACTUAL CAUTERY IN THE TREATMENT OF CORNEAL ULCERS.[1]

By WILLIAM E. BRUNER, A.M., M.D.,

CLEVELAND, OHIO,

CONSULTING OCULIST TO THE CLEVELAND CITY HOSPITAL, AND CLINICAL ASSISTANT IN OPHTHALMOLOGY IN THE MEDICAL DEPARTMENT OF THE WESTERN RESERVE UNIVERSITY.

SIMPLE corneal ulcers, and fortunately the majority of them are such, present few difficulties in their treatment. A simple eye lotion, or that together with atropine, will not infrequently be sufficient. If there is no associated conjunctivitis or lacrymal trouble, an occlusive dressing will produce more rapid healing than any other treatment, by its protection of the eye from all irritation, even that of the movement of the lids over the inflamed surface. On the other hand an associated conjunctivitis may be the chief factor in keeping up the ulcerative process, as it serves as a constant source of infection to the denuded area. Then a few applications of silver nitrate (one-per-cent. solution) to the lids will be most efficacious. Or pathologic conditions of the nose, nasopharynx, nasal duct, or lacrymal sac may serve as the source of infection and will require attention.

Antiseptics applied directly to the surface of the ulcer often prove very helpful. Various ones, as silver nitrate, pure carbolic acid, tincture of iodine, formalin, and others, are used. For some time I have been employing bichloride of mercury (1–500) with very gratifying results in many cases. It will usually be well first to instil a few drops of a solution of cocaine, and then with a fine cotton swab moistened with the strong solution touch the ulcer gently, or more vigorously if there is a slough on its surface. I have seen prompt improvement with this treatment in many cases which had not responded to other treatment.

Remedies, too numerous to mention, are constantly being tried. Iodoform certainly acts well in some cases. The old "standbys," calomel and Pagenstecher's ointment, are still used and found serviceable in certain stages of phlyctenular ulcers, and eserine should not be forgotten as a very valuable adjuvant in some cases. It is, however, of the more severe types of ulceration that I wish to speak, those in which possibly the simple remedies have been tried without beneficial effect, or when it is evident upon the first visit that something more radical will be necessary. Of course we must never forget the constitutional condition and hygienic surroundings of our patient, in mild as well as in severe cases, as we may here find the "key to the whole situation." Neglecting to pay attention to the patient's general health, or to the diet, amount of fresh air and exercise, and other hygienic conditions, we may find that all our local treatment proves ineffectual; but on the other hand, if we regard only the general condition of the patient and neglect the local treatment, we may find that ere the general health can be improved the cornea may be irreparably damaged. Our constitutional remedies often act slowly, while it is frequently necessary to obtain some prompt local effect upon the ulcer if we wish to stop its progress and preserve a useful eye.

Curetting has been much practised in the severe cases, but I confess not to have had so good results with the curette as with the actual cautery. Before speaking of that, however, I wish to mention one treatment used especially by the French ophthalmic surgeons for these severe ulcers, and that is subconjunctival injections of various solutions. The usual method has been to inject two or three minims of a 1–1,000 solution of bichloride of mercury beneath the conjunctiva, and repeat every two or three days as may be indicated. The good results were supposed to be due to the disinfecting and antiseptic action of the solution. Gradually the strength of the solution has been reduced, until now a 1–4,000 solution is preferred by many, and the opinion is becoming more prevalent that the efficacy is due to the fluid itself in causing an acceleration of the lymph currents of the cornea.

The experiments of Mellinger and Bossalino would tend to confirm this theory. Acting upon this principle, Marti and others have been using a solution of sodium chloride, as being equally efficacious and less irritating than the mercury, and they report very good results.

Still clinging to the idea of antisepsis, but thinking that possibly the acceleration of the lymph current in the cornea or circulatory modifications resulting from the injections may play a part in the result, De Wecker, Scalini, and others still use an antiseptic solution, but make large injections instead of only two or three minims, and claim results such as they never obtained with the small injections.

In the hands of the majority of oculists, however, greater dependence is placed in severe corneal ulcers upon the actual cautery, and certainly my own experience with it has been very gratifying.

As early as 1873 Martinache recommended it in hypopyon keratitis, and about the same time Samelsohn advised it in affections of the lacrymal apparatus, conjunctiva, and ciliary border. Later Fuchs and several others advocated its application to the corneal tissue, but it was slow in gaining favor until Nieden, Schweizzer, Knapp, and Gruening published their results. Since then its value has been recognized by all oculists, though some may use it much more frequently than do others.

There are various types of ulceration in which it is especially valuable, but the simple fact of there being an ulcer should not be considered sufficient excuse for using the cautery. In other words it should not be used indiscriminately, but should be reserved for selected cases in which the simpler methods have been tried and have failed, or occasionally in severe cases in which even upon the first visit it is evident that something radical will be necessary.

In abscess of the cornea the cautery is now often used when formerly the Saemish section would have been practised, and I have seen most gratifying results follow.

In serpiginous ulcer this is the most effective means we possess of stopping its advance. A sloughing ulcer with its surface covered with pus, threatening either to involve more and more of the corneal tissue, or to perforate, will after a thorough cauterization take on a healthy appearance. Usually a single application will be sufficient, though rather than attempt to use it too vigorously the first time it is better to use it a little more cautiously and then repeat, if need be, in a few days. We should, however, endeavor to destroy the dead and purulent material as thoroughly as possible without destroying any of the healthy tissue. In the sloughing ulcer associated with pus in the anterior chamber—hypopyon keratitis—the application of the cautery will often cause the purulent material to undergo absorption.

In chronic ulcers which have resisted possibly for a long time all forms of treatment, touching once with the cautery will frequently change entirely their character and produce speedy resolution.

In phlyctenular ulcers, herpes of the cornea, and many other forms of ulceration, this remedy will at times prove invaluable, and by its use not a few eyes, which would otherwise most probably be lost, are saved, and that, too, with good or fairly good vision.

Its application would be contraindicated when

[1] Read before the Cleveland Society of Medical Science.

perforation has taken place and the iris is prolapsed or attached to the edges of the ulcer; and also in very extensive ulceration of the cornea when a thorough cauterization would be apt to cause too severe reaction.

The galvano-cautery and the Paquelin thermo-cautery are usually spoken of as the best instruments for this purpose, and they certainly are the most elegant. More simple and less expensive ones will, however, be found to answer the purpose just as well. I have a platinum tip in a wooden handle, and use an alcohol lamp for heating it. Cocaine anæsthesia is sufficient and renders the operation entirely painless, but in small children it is well to use a general anæsthetic. Fluorescin will be found of value in some cases in exactly outlining the extent of corneal surface which is denuded of epithelium. Heroic as this treatment may seem, I have never seen a bad result follow its use. The relief from pain, which frequently follows the use of the cautery, is very marked, though sometimes there will be a slight exacerbation for several hours. Any of a number of cases will suffice to illustrate its application.

Case I.—Mrs. M. S——, aged thirty-one years, was referred to me by Dr. Bunts, with the history that for seven weeks she had been suffering with her right eye. There had been some discharge, sight had become impaired, the eyeball pained considerably, and a dull headache was almost constantly present. Examination showed an ulcer at the outer margin of the pupillary area of cornea, with considerable loss of substance, and with infiltration about it. There was also some catarrhal conjunctivitis. Under the use of the usual remedies, together with silver nitrate, the eye improved until about a week later, when some dust got into it. I found some foreign substance resting upon the ulcer, which was looking considerably worse. This was removed, the ulcer gently curetted and touched with bichloride of mercury (1–500), and the eye bandaged. No improvement took place, and four days later the actual cautery was lightly applied. The eye felt decidedly better and the ulcer improved, except in one very small spot, which was again touched with the cautery. Improvement then continued without interruption, and when I last saw her, ten months after the inflammation had subsided, vision, with some astigmatism corrected, was $\frac{5}{9}$.

Case II.—F. R——, aged thirty-five years, consulted me at the college June 17th, with the history that the left eye had been inflamed for three or four days. Examination revealed a small ulcer at the upper outer portion of the cornea. A simple lotion was given. A week later he returned with a fresh attack of inflammation. Atropine was instilled and a bandage applied. On the 29th, the ulcer, which had continued in about the same condition, with very little inflammatory reaction, began to take on a somewhat serpiginous character, extending toward the centre of the cornea. The actual cautery was applied with decided benefit, but after a few days, as the apex of the advancing portion again looked unhealthy, the cautery was applied simply to that portion. Following this, the ulcer rapidly became healthy in appearance and was very soon entirely healed.

Case III.—Mrs. K. D——, aged twenty years, consulted me, with the history of frequent attacks of inflammation in the eyes since childhood. The present attack had lasted four days. There was a small phlyctenula beyond the limbus in the right eye, and in the left there was an ulcer almost in the centre of the cornea, with considerable pericorneal injection. The patient was rather anæmic. Atropine and a simple lotion were ordered for local use, and syrup of iodide of iron for internal use. She was also referred to Dr. Straight, who found posterior adenoids, as suspected, and removed them. Two days later the eye was looking no better, in fact rather worse, and the ulcer, or rather abscess, for the epithelium covering it was found still to be intact, was a little larger. Under cocaine the cautery was applied rather freely to the surface of the abscess. Three days later the eye was so much better that the bandage was removed, and within a week all signs of inflammation had disappeared.

Though I might cite other cases, these few are sufficient to indicate the value of this remedy in purulent inflammation of the cornea; and while we should not be too hasty in applying it in all cases, yet on the other hand we should not err by postponing too long, until the ulcer becomes larger, the use of this most effective means of stopping its progress. When the cautery is properly applied no more dense scar will remain than would be produced by the ulcer itself, and in fact by its timely use we can often prevent the formation of a large scar.

CHRONIC SUPPURATIVE OTITIS MEDIA.[1]

By ROBERT E. MOSS, M.D.,

San Antonio, Texas.

The practical interest to the aurist and general practitioner, and its serious termination when neglected, make this disease one of great importance. It has been greatly neglected in the past, and, I might say, is still, and it is only in the last few years that it has been treated on a rational basis. We are told quite frequently by patients who have suppurative ears, especially children, that the doctor said they would outgrow it. In order intelligently to treat any lesion or diseased condition, it is necessary first to determine the cause or causes producing the same, the location and extent of the diseased process. As a cause, we find that the condition known as adenoids heads the list, for this in childhood leads to acute suppuration, which recurs from time to time as the lymphoid tissue in the nasopharynx becomes swollen from colds, producing pressure upon the tubes of either side, or maybe only one, and this causes temporary or permanent occlusion of the Eustachian tube. This is followed, of course, by acute suppuration, unless promptly relieved, and may continue as a chronic process: or as the pressure is relieved the tube becomes patent, and the discharge ceases, to recur again with the next severe cold. As a consequence of this, we have permanent changes occurring, which serve to keep up a discharge. Tuberculous caries is rather frequently met with, or, at least, we see quite a number of these unfortunates in this locality. Whether it begins as such, or is, as I believe, engrafted upon an existing diseased condition, I do not know.

This form of suppuration is the most difficult of all to deal with, for in the majority of cases there is advanced tuberculosis of the lungs, and we are not justified in advising these subjects to submit to surgical procedures unless there are positive indications of serious complications.

Cholesteatoma is not an uncommon cause, but requires radical treatment. Granulations, polyps, caries, necrosis, and at times a foreign body, are found as immediate causes of the persistent discharge. The exanthematous fevers are also frequently followed by prolonged suppurative processes involving all the important structures of the ear. It is impossible to form any definite idea of the condition of the middle-ear space, antrum, and mastoid, from the appearance or symptoms complained of by the patient. The small perforation in the tympanic membrane, with

[1] Read before the Southwestern Texas Medical Society, October 29, 1896.

slight discharge and more or less pain, is all we have to call our attention to the ear. There is usually some impairment of hearing, and this may amount to complete deafness; yet the degree of impairment, tinnitus, pain, and discharge are not safe guides to inform us of the extent or location of the diseased process. I have found, when operating, extensive involvement of antrum and mastoid, the cells crowded with granulations, caries of bone, the pus overflowing into the middle ear and making its exit through perforation in the tympanic membrane; yet there was not a symptom which would aid us in deciding that such a condition existed.

It is well to make a very careful examination in every case, getting a complete history, and never omitting an examination of the eyes with the ophthalmoscope, for statistics show that at least fifty per cent. of cerebral abscesses are caused by suppurative ear troubles, and if we find choked discs our prognosis should be guarded and immediate operation advised. In treating any case, our first duty is to remove every possible cause and then direct our treatment intelligently to the diseased area. It is impossible to formulate any plan of treatment suitable for all cases.

We frequently see an article from an enthusiast, recommending some plan as a cure-all and he seldom admits a failure. I can only say of such that they are not safe men to follow. If we should treat our cases from the standpoint of advanced surgery, and not rely upon powders, astringents, washes, douches, etc., our successes would be far greater.

In giving the details of treatment, I shall not tax your patience with long descriptions of the plan of this or that man, but briefly outline the histories of a few cases treated, which fairly include the types most frequently met with.

Case I.—H. L——, aged one year, had a history of discharge since he was three weeks old. He was very small, poorly nourished; lymphatics everywhere enlarged; tonsils hypertrophied; nasopharynx completely filled with lymphoid tissue. The right ear was swollen, with redness and œdema over the mastoid region. The dischage from the external canal was scant but very offensive. The left ear showed no swelling. The discharge was rather profuse, but without odor. He had fever running from 100° to 103° F., which had lasted about a week. The child cried almost continually, unless he was under the influence of some narcotic. The attending physicians had been giving the child the benefit of the best recognized treatment for such cases, and the condition was growing worse. I advised an immediate operation, which was done the same day. I chiselled down to the antrum on the right side, and found caries of the walls, with masses of granulation tissue, all of which were thoroughly removed. The cavity was carefully syringed out with saturated boric-acid solution, then dried and dusted with iodoform, and the external incision closed. Then I removed the tonsils and all lymphoid tissue from the nasopharynx. He recovered nicely from the operation, and was free from fever upon the second day, taking more nourishment and resting quietly without an opiate. I prescribed calomel triturates and iodide of iron, with cod-liver oil. He made a perfect recovery. His hearing is normal, and he is still free from any trouble. Operation, three years ago.

Case II.—Wallace P——, aged sixteen years, had had suppuration of right ear since an attack of measles fourteen years before. He had been treated by a number of physicians, and I treated him faithfully for two months, without any improvement, and advised an operation. In chiselling down to the antrum, I came upon the lateral sinus not more than one-sixteenth inch from the wall of the external canal. It was nicked, unfortunately, and I had to pack with sterilized gauze to check bleeding. The tympanic membrane had been destroyed and the hearing also of that ear; therefore, I curetted carefully all diseased bone I could detect, which extended to the dura above the middle-ear space. The cavity was irrigated very gently, with head held well over; then dried, and thoroughly insufflated with boric-acid powder. The gauze packing was removed two days later, and the wound closed. He had facial paralysis on the same side, which is an unfortunate but not always avoidable complication. This was treated with mild faradic current, and at the end of three months it was noticeable only when he laughed. The discharge entirely ceased, and he was also completely relieved of severe headaches, from which he had suffered at times for years.

Case III.—J. P——, aged thirty years, had had suppuration of both ears since childhood. Right, he heard a watch in contact; left, a loud voice at two feet. I treated him most thoroughly for three months, and the discharge ceased in the right ear, but no improvement was noted in the left. I performed a Stacke operation on the left ear, and found the mastoid cells and antrum filled with granulations, and the bone necrosed. The discharge and tinnitus were completely relieved by the operation, and the hearing was improved so that the watch is heard now by light contact.

Case IV.—H. K——, aged twelve years. Double suppurative otitis following scarlet fever. Examination showed large perforation in the tympanic membranes of both ears, offensive discharge, and masses of granulations seen through perforations. The pus was forced out by Politzer inflation and careful use of the masseur; the cavity was cleansed, cocainized, and dried; and nitrate of silver, one drachm to the ounce, was carefully applied with a slender cotton applicator. This was allowed to remain a few moments, then neutralized by salt solution. There is a good deal of pain, but I have never seen any dangerous reaction follow this procedure. The nose and nasopharynx received attention in the mean time. At the end of three months all discharge had ceased, and by touching the margins of perforation in the tympanic membrane of the left ear with nitric acid once a week, it was completely closed. The right is too large ever to close, as at least two-thirds are destroyed. Hearing: Right ear, $\frac{3}{36}$; left ear, $\frac{34}{36}$.

In studying the relation which chronic suppuration of the ear bears to cerebral abscess and sinus thrombosis, we are impressed with the great importance of these cases and how imperative is the thorough removal of the cause.

There are very few cases of long standing in which we are not justified in performing the Stacke operation, provided, of course, every visible cause has been removed and the discharge continues. We are advised by some to wait until there are urgent symptoms pointing to extension of the trouble before resorting to operation. What would we think of a general surgeon today who would try palliative remedies in a case of recurring appendicitis or circumscribed peritonitis due to pus tubes? And yet patients afflicted with either of these latter conditions may live years after the death of one with suppurative otitis.

Those of us who have been unfortunate enough to operate after the meninges and brain were involved in a septic inflammation realize how futile are such efforts. It would be like telling the experienced abdominal surgeon to wait until there were symptoms of perforation or peritonitis before opening the abdomen. The operation should never result fatally when done by a skilled operator and one thoroughly familiar with the parts involved. The oftener I operate the more pronounced is my opinion that many lives might be saved each year by operating in every case that has resisted intelligent thorough treatment.

Progress of Medical Science.

The Chemistry of Human Breast Milk. — From a clinical and chemic study of the breast milk of two hundred recently delivered women, Adriance and Adriance (*Archives of Pediatrics*, February, 1897, p. 85) conclude that an excess of fats or of proteids may cause gastro-intestinal symptoms in the nursing infant. An excess of fats may be reduced by diminishing the nitrogenous elements in the mother's diet, and an excess of proteids by the proper amount of exercise. An excess of proteids is especially prone to cause gastro-intestinal symptoms during the colostrum period. The proteids, being more abundant during the colostrum period of premature confinement, are a source of danger to the untimely born infant. Deterioration in human milk is marked by a reduction in the proteids and total solids or in the proteids alone. This deterioration takes place normally during the later months of lactation and, unless proper additions are made to the infant's diet, is accompanied by a loss of weight or a gain below the normal standard. When this deterioration occurs earlier it may be the forerunner of the cessation of lactation, or well-directed treatment may improve the condition of the milk.

The Treatment of Disabled Joints Resulting from the So-Called Rheumatoid Diseases.—In a recent communication, Goldthwait (*Boston Medical and Surgical Journal*, January 28, 1897, p. 79) reports a series of cases which for convenience' sake he considers under two types—rheumatoid arthritis and osteo-arthritis, to the differentiation of which he attaches much importance from a therapeutic point of view. Rheumatoid arthritis is said to be much more acute than osteo-arthritis; it occurs in middle and advanced life and in early life as well. During the acute stage the joints present a spindle-shaped swelling, which finally subsides, leaving the joint much atrophied and usually ankylosed. In the treatment of cases belonging in this category the joints should be manipulated after all acute symptoms have disappeared. The character of the manipulations is of much importance. Osteo-arthritis is a much more chronic condition, occurring only in middle life or old age, and is characterized by a proliferation of the articular cartilage, with the formation of nodes about the joints. In cases of this kind manipulation should not be practised, as any injury or undue violence is likely to stimulate a more rapid development of the cartilage. It is this tendency that explains the impairment of function that so often results after comparatively simple injuries to a joint. Under such circumstances protection and immobilization are of importance.

Tuberculosis in Infancy.—In a paper having special reference to the mode of infection in tuberculosis of early childhood and infancy, Dr. L. Emmett Holt (*Medical News*, December 12, 1896) concludes: 1. Intra-uterine infection in cases of tuberculosis is very rare, the child often escaping even when the mother is suffering from active disease in an advanced form. 2. Infection through the alimentary tract is also very rare, and will not explain more than one or two per cent. of the cases. 3. The distribution of the lesions in tuberculosis of infancy and early childhood points conclusively to infection in the vast majority of cases through the respiratory tract.

Facial Tic as an Occupation Neurosis.—At a recent meeting of the Berlin Society for Psychiatry and Nervous Diseases, Cohn (*Berliner klinische Wochenschrift*, January 4, 1897, p. 16) related the case of a man, forty-eight years old, who had worked as a watchmaker for thirty-four years from eight in the morning until eight or nine at night, during most of the time holding in his left eye like a monocle a lens in a wooden frame. For two years there had been twitching about the left eye and the adjacent part of the face. The movements occurred at first only after the man had been at work for some time, but they gradually became constant and were sometimes tonic in character. The disorder was not reflex through the trigeminus, as there had never been pain or other manifestation in the distribution of that nerve, but it was considered as an occupation neurosis resulting from the continued excessive innervation of the facial nerve.

Uretero-Ureteral Anastomosis.—In a paper read before the Southern Surgical and Gynecological Society, Bovée (*Annals of Surgery*, January, 1897, p. 51) maintained that uretero-ureteral anastomosis is a perfectly feasible procedure, which, whenever it is possible, is far preferable to any other form of ureteral grafting, to nephrectomy, and to ligation of the ureter. It should be done preferably by lateral implantation or by oblique end-to-end anastomosis, though the transverse end-to-end or the end-in-end method may be employed safely. Constrictions of the calibre of the ureter do not usually follow attempts at suturing in closure of complete transverse section of the duct. Nephrectomy for transverse injuries of the ureter *per se* is an unjustifiable operation. Simple ligation of the ureter to produce extinction of the function of the kidney is too uncertain to justify its practice. Drainage is not necessary if the wound be perfectly closed and the tissues throughout are aseptic.

The Intraperitoneal Treatment of Abdominal Hydatids.—This new method seems to be gaining ground in Australia, as a result of further experience, and justly so. The usual treatment has up to date been that well known by the name of Lindemann's operation, consisting of laparotomy, evacuation of cyst contents, and suturing of the adventitious sac to the wound, followed by drainage. This operation has been condemned in able articles by Mr. Hamilton Russel and Charles Ryan as unscientific and unnecessary. The former points out that there is absolutely no reason for treating the sac with this amount of consideration; that for all practical purposes, the sac is only the capsule which necessarily forms round a foreign body, and that when the foreign body which has excited its formation has been removed the adventitious sac may be disregarded and dropped back into the depths of the wound, and the wound closed completely, as after any ordinary abdominal operation. Mr. Russel then discusses the objections which have been urged against this intraperitoneal method. The first objection is that the fluid poured out from the adventitia will escape into the peritoneal cavity. His answer to this is that, in the first place, there would seem no reason to suppose that any large amount of fluid will be poured out by the adventitia; in the second place, the best thing that could happen to any fluid so poured out would be that it should escape into the peritoneum, for, being an aseptic fluid, it could do no harm to the latter, but would be rapidly removed by absorption. In this also lies one of the chief objections urged by Mr. Russel against suturing the opening in the sac, as was done by Bond, of Leicester (who really made the first departure from Lindemann's method), for, the sac being a structure which has absorptive powers very inferior to those of the peritoneum, the fluid would not be removed so rapidly,

and would therefore be in a much more favorable position for the occurrence of decomposition, should the elements of septic change have been introduced at the time of the operation. For these and other considerations several surgeons have now successfully adopted for all non-suppurating cases of hydatid the intraperitoneal method, which briefly consists of laparotomy, then incision into the tumor, removal of the mother cyst and all membrane, cleaning and wiping dry the cavity with sponges, and finally dropping back without any suture the adventitia, and final closure of the abdominal wound. The only sound objection that I can see to this method is that bile might (as it sometimes does) escape from a bile duct into the sac and lead to mischief, but so far no bad results have happened.—*Australasian Medical Gazette.*

Cardiac Surgery.—An editorial writer in the *Journal of the American Medical Association* points out that wounds of the heart or pericardium are by no means inevitably fatal. Thus Steudener relates a case of a man who was shot through the heart and the bullet ranged backward through the spinal cord, causing paraplegia. Death occurred in fifteen weeks, evidently more from the latter cause than from the heart wound. In West's case a man received a stab from a shoemaker's knife. After remaining in the hospital for a month he was discharged, and died from tuberculosis four years afterward. Professor Conner, of Cincinnati, relates a case of a boy, aged fifteen years, who was shot from behind. Pneumonia, endocarditis, and pericarditis developed, and after thirty-one days the patient was able to walk. A valvular lesion remained as a result of the endocarditis, and death occurred three years and two months afterward. These cases were confirmed at the necropsies. Even more remarkable are the cases reported by Velpeau and Brugnoli. In the former's case a man of fifty came to the necropsy table with a history of having received a stab in the left breast from a table knife some nine years previous. At the examination scars were discovered both in the pericardium and in the right auricle, with adhesions between. Brugnoli records the case of a man who, after receiving a stab from a knife, was able to resume work in seventy-eight days, and lived for nineteen years. The necropsy disclosed an enlarged heart, an adherent and calcareous pericardium, and old scars in the right ventricle and septum, with a split mitral valve. The heart is an organ that sometimes tolerates foreign bodies very well, and again a slight injury gives rise to a fatal issue. Among foreign bodies found in this organ besides bullets and needles, which are the most common, are splinters of wood, fish bones, etc. Even the ubiquitous hat pin has been discovered (Langier). Bullets have been found encapsulated in the heart for many years; in the right ventricle six years (Latour); in the wall of the ventricle for twenty years (Balch); and for no less than fifty years in the pericardial sac. It must be observed in passing, however, that these cases refer to the old-fashioned round balls: few conical balls will be stopped by the heart, and still fewer, if any, of the most recent projectiles of small calibre and extreme penetration. The extent of the wound does not seem to bear any decided relation to the duration of life, for while Steiner's experiments seem to prove that simple puncture by a needle is not very dangerous, yet several cases are on record of immediate death resulting from needle wounds, either accidental, homicidal, or otherwise. Again, in the cases in which recovery took place, as previously mentioned, the damage was much greater than any that could be inflicted by a needle. In Brugnoli's case the mitral valve was implicated: in Conner's, one cusp of the aortic valve; yet the patients survived for years. The causes of immediate death after heart injuries are two in number, nervous and mechanical. First, by interference with the ganglia presiding over the movements of the organ, and second, by the effusion of blood into the pericardial sac, thus compressing the organ and hindering its action. For the former complication surgery is of no avail. In the latter, however, it would seem that evacuation of the fluid or clotted blood might be followed in many cases by favorable results. Although paracentesis of the pericardium was first proposed by Riolan over two centuries ago (1649), it was not until late in the present century that it was actually put into practice. Roberts reports over forty per cent. of recoveries after paracentesis or incision, and, bearing in mind the usually fatal ending of the affections requiring this operation, the figures are highly encouraging. Possibly these favorable results have encouraged surgeons to advocate suturing bullet and stab wounds of the pericardium and heart. Park, of Buffalo, we believe, is the latest of these. It has remained for Cappelen to put this suggestion into practice. The patient was a man of twenty-four, who had received a stab from a knife some hours before admission. On entrance he was unconscious, no pulse could be felt, the heart sounds could be heard, but no impulse was perceptible. The wound was a puncture, not bleeding, one centimetre long, and situated in the left fourth space, parallel with the rib. After an injection of camphor the patient began to breathe and the pulse could be felt. The left side of the chest did not move. Under chloroform the wound was enlarged, and the fourth rib was resected. The left lung was compressed by an accumulation of blood in the pleural cavity, partly fluid, partly clotted. After this was evacuated the lung expanded and was found to be not wounded. The third rib was now resected and a wound which was bleeding freely was found in the pericardium, one centimetre long. The pericardial sac was found to be filled with coagulated blood, and after the wound in the pericardium was enlarged another one measuring one centimetre in length was found in the left ventricle, which caused the hemorrhage. This wound was sutured and an artery tied, when the bleeding ceased. The account of the operation states that the suturing was rendered extremely difficult by the rhythmic movements of the lung, which covered and obscured the field of operating, and by the contractions of the heart, which, however, were quiet and regular. The suturing was accomplished by bringing the needle half way through during a contraction, then dropping it, and after second contraction bringing it completely through. After the operation the patient's pulse was very rapid and feeble, but improved after saline injection. The patient sank gradually and died two and one-half days later. The necropsy showed a wound of one of the large branches of the coronary artery; the wound had healed partially, but there were a beginning pericarditis and various bacteria in the exudate. While death ensued, yet the fact that the patient lived for over two days, and that no operative measures could be instituted for some hours, shows that in more favorable cases recovery will follow. Fischer's statistics prove that the most important parts of the heart functionally, the ventricles, are much more liable to wounds than the auricles—two hundred and fifty-seven wounds of the ventricles against only thirty-one of the auricles, a result which might be expected from the smaller size and less exposed position of the latter. Again, the great urgency of similar operations may preclude as thorough aseptic precautions as those in other measures of less expediency. However, in view of the foregoing facts the opinion seems warranted that "the citadel of life" itself will no longer be exempt from the incursions of the surgeons.

New York, February 27, 1897.

IS GYNECOLOGY DESTINED TO BECOME AN OBSOLETE SPECIALTY?

THE phenomenal interest in gynecology manifested by the profession during the past few years has been shown not only by the flood of special literature annually poured out and by the number of societies devoted to this branch of surgery, but by the fact that young men are crowding into this specialty to an extent which warrants the inference that the supply already exceeds the demand. Moreover, the prominence which has been given to gynecology in all our post-graduate schools, where it has always been the popular subject, has tended not only to increase the special knowledge of the general practitioner, but to lead him to believe that any one can be a gynecologist. We have frequently in these pages deplored the ultra-surgical trend of this specialty, and have predicted that a reaction would come. Such has been the history of every American fad which has been pushed to its extreme limits, whether in medicine or in fashion. This reaction has already set in, as shown by the conservative practice and teachings of men who were formerly most radical in their methods.

But, unfortunately, the attempt unduly to exalt gynecological surgery at the expense of non-surgical treatment has reacted somewhat disastrously upon gynecologists themselves. Not content with confining themselves to their proper region, they have reasoned that their familiarity with abdominal surgery should render them the equals if not the superiors of general surgeons in the handling of cases which bear no relation to diseases of the pelvic organs.

We shall not discuss the propriety of this tendency to broaden the sphere of gynecological surgery, or seek to deny that special operators have been remarkably successful in general surgery, but would merely call attention to the fact that gynecologists have only themselves to blame if general surgeons have followed their example and now perform all the operations which they formerly left to their confrères. The natural process of reasoning has been: If gynecology has become purely surgical, why should it be confined to a special class of operators, who themselves no longer devote their attention exclusively to pelvic diseases?

But this is not all. We observe with regret that a decided antagonism has developed between the gynecologist and the general surgeon, as shown by frequent unfriendly comments in published addresses, society discussions, and even after-dinner speeches, each accusing the other of invading his territory and performing special operations with which he is unfamiliar. Now, as the surgeon is decidedly in the majority and is closely in touch with the general profession, the specialist is manifestly at a disadvantage and must look to himself or he will "lose his grip." It will be his own fault if the noble branch of surgery which has been enriched by the labors of so many master minds ceases to occupy the commanding place which it has held so long.

How is it that this change has come about in America, when abroad the distinction between gynecologist and general surgeon is just as sharp as ever? It appears to be due to some extent to the fact that the commercial factor has become prominent, to the exclusion of the scientific. The brilliant spectacle of the operating-theatre has been regarded as more attractive than the more solid results of the laboratory. Pathology has given place to improvements in operative technique. In short, gynecologists have been so anxious to devise new surgical methods of treating every pelvic trouble that the fact has been largely lost sight of that important pathological questions still remain as far from solution as they were ten years ago. If gynecology is to remain a specialty it must be because its followers continue to demonstrate the fact that they can do their own work better than general surgeons, and, moreover, that in many cases in which the latter overlook the more occult conditions they can by their greater knowledge and skill preserve organs which the surgeon would sacrifice. It is along the line of conservatism that the battle will be fought, not of radicalism. It would be well for the coming gynecologist to bear this in mind, as well as the little-heeded advice not to launch out as a specialist without a thorough general training. Gynecology is a natural outgrowth of general surgery, but the contrary is far from being true, and any attempt to reverse this condition must end in ultimate failure.

Let gynecologists prove that their specialty is capable of development along other lines besides those of radical surgery, and there is no danger that it will ever come to be regarded as unnecessary.

THE HEALTH BOARD AND COMPULSORY REPORTS.

THE committee on hygiene of the Medical Society of the County of New York made the following report on Monday evening, endorsing the recent mandate of the health board concerning compulsory notification of cases of pulmonary consumption:

"Realizing the need of proper measures to prevent the spread of pulmonary tuberculosis, and regarding it an essential preliminary that all physicians be impressed with the importance of making an early diagnosis of the same by microscopical examination of the

sputum, we earnestly recommend that physicians avail themselves of the offer of the bacteriological department of the board of health to make such examinations. We approve of the compulsory reporting of cases of pulmonary tuberculosis, if the inspectors are forbidden to visit or to have any communication with the patients without the consent of the attending physician, believing that the attending physician is capable of giving all the necessary instructions.

"W. H. Katzenbach, M.D.,
"*Chairman.*
"Charles N. Dowd, M.D.,
"E. Le Fevre, M.D.,
"Robert C. Myles, M.D.,
"D. Harris, M.D."

Considering the great significance of the proposed compulsory measure and the widespread professional opposition to its practical enforcement, the report in question can hardly be considered as expressing the views of the rank and file of the medical fraternity. Fortunately for the society, the recommendations were laid upon the table for future discussion.

Every one realizes the necessity of preventing the spread of tuberculosis, but concerning the means to the end there is a very radical difference of opinion between the board and the profession at large.

It is hardly necessary in these days to impress the physician with the importance of an early diagnosis of this very common disease. In fact, the insertion of such a recommendation in a report calculated for public use would naturally imply that physicians as a rule are not careful enough in their early diagnosis of this disease to be trusted absolutely, and that consequently the bacteriological department of the health board must come to their assistance. Virtually to the health board is thus given the controlling power in the making of a diagnosis. It becomes a very serious question whether or not everything in the way of the early recognition of the disease actually depends upon the discovery of the tubercle bacillus in the sputum. As a matter of fact, we know that this is not so. With tubercle bacilli everywhere, there is no reason why they should not exist, temporarily at least, in the pharyngeal or bronchial mucus of even healthy persons. It is the taking root in a depressed vitality that fixes the thing. When the latter is done, the diagnosis is simple enough. The signs obtained, even in the earlier stages, are easily enough recognized by the merest tyro in auscultation. The localized dulness at the apex, the prolonged, high-pitched expiratory murmur, the circumscribed râles, the hæmoptysis, and the dry hacking cough are too significant to leave any doubt in the mind of the most casual observer. The bacteriological examination is merely confirmatory of what has already been discovered. To make it the one absolute test is absurd. It is, in fact, magnifying the importance of such a test beyond all reason for its real necessity. Besides, it is the confession of an inability on the part of the family attendant to make a diagnosis without outside help.

Which, then, becomes the higher authority? If clinical experience avails nothing, then each medical man should have his own laboratory, for certainly all our patients should have the best advantages for diagnosis and treatment that can be obtained. Then, again, the profession should consider how much of increased responsibility and of unnecessary work is thus thrust upon an ever willing board. What has happened with the tuberculous question may likewise occur with any other disease, and where are the appropriations to be obtained for new official hospitals, larger official laboratories, and more official inspectors? Already we see that the force of the latter is wholly inadequate to stop the constant spitting in cars and other public places. It may be possible, too, that the board with all its power may even find that the present compulsory reports of phthisis cases may be equally impracticable.

This will certainly be the case unless some compromise is effected between the power of the board and the rights of the profession. There is no objection to the reports of pulmonary cases for statistical purposes. In fact, every medical man would be willing to conform to such a reasonable request. It is, however, the extra missionary work assumed by the board which is the ominous and threatening quantity in the equation—the desire to assume official control of the cases after they have been reported, thus not only, by means of alarming bacteriological edicts, directly interfering with the physician in the diagnosis and treatment of the patient, but in the end, by the creation of a public suspicion of his ignorance, possibly depriving him of one of the means of a legitimate livelihood.

The attempt of the committee to reconcile the opposing conditions of might and right of compulsory reports, by the qualification that the inspectors shall not visit phthisical patients without permission of the physician, is, under present circumstances, inconsistent and illogical, and is barely excusable on the ground of trying to say something and meaning nothing. The board has the power to do as it sees fit. If it chooses to make an inspection it can do so, all protests of the physician to the contrary notwithstanding. The only basis of a proper understanding in this matter is the guarantee of the board that in case the returns of pulmonary cases are faithfully made, for statistical purposes only, there shall be on its part no direct or indirect interference between patient and physician, either in the way of official inspections, bacteriological diagnosis, forced isolation, suggestions for treatment, or presumptuous instructions to the patient regarding hygienic precautions. If we mistake not, the profession is very much in earnest in thus dividing responsibilities with the board, and will yet be able to vindicate its rights and demonstrate its power.

We doubt not that these and many other points bearing on the proper relations of the health board with the profession will be duly discussed at the next meeting of the society. The sister organization, the New York County Medical Association, as will be noticed in a report in our present issue, is also interested in this question, and will at its next meeting doubtless speak its mind in no uncertain tone.

THE COCAINE HABIT.

By a curious coincidence there have been references lately in several of our contemporaries to an alleged increase in cocaine addiction in various sections of the country. Contrary to what is supposed to prevail in regard to vices of this sort generally, this habit seems to have obtained a hold over the working members of the community, the idle and the vicious apparently preferring opium and alcohol and other poisons. In an editorial on this habit, which it calls a "*fin-de-siècle* curse," the *Memphis Medical Monthly* says that in the South by far the greater number of sufferers are to be found among the lowest element of the negro population, although there are many other laborers and people of a higher class who have fallen victims to the habit. It is stated that in one shop alone about ten dollars' worth of cocaine is sold every night in ten-cent packages of five grains each. In New England also the vice is widespread. The *Boston Medical and Surgical Journal* says, quoting from the daily papers, that such large numbers of the inhabitants of Manchester, Conn., have become slaves to the cocaine habit that, in the opinion of an "experienced physician," "the future prosperity of the town is involved." The trouble arose from a preparation of cocaine and menthol which a druggist in the town compounded about a year ago, and exploited as a remedy for asthma. So popular has this "snuff" become that people are seen in the streets and in dark corners at public entertainments indulging their passion for the compound. According to the report, the druggists, although getting rich by the sale of the compound, are so bothered by "well-known men and women" who ring them up at all hours of the night to obtain a supply, threatening to break into the store if their wants are not attended to, that they have become prime movers in an attempt to check the evil habit. Numbers of people are said to be running into debt to provide themselves with the drug.

Making all allowances for reportorial exaggeration, we have no doubt that many people in all parts of the country are being innocently lured into this enslaving habit by the catarrh "snuffs" and "balms" so extensively advertised. Many of these do, of course, afford temporary relief, and they are therefore resorted to with each recurring attack of coryza and are charitably recommended to friends. And so imperceptibly the victims come to rely upon the preparation for daily stimulation, and by the time that they have learned that it is the cocaine that helps them they are already powerless to free themselves.

A Suit for Using X-Rays.—A Chicago pugilist has brought suit for damages against a surgeon for locating a bullet by the *x*-rays. The plaintiff alleges that the surgeon kept his body exposed thirty-five minutes to the rays; that he suffered much while the bullet was extracted, and as a result a sore on his breast two inches in diameter has developed, which will probably never heal entirely. In order to make the punishment fit the crime, he asks for damages to the amount of *x* thousand dollars.

News of the Week.

Dr. Kammerer's Article.—In Dr. Kammerer's very interesting article in our last issue, Figs. 1 and 2 were accidentally misplaced. We trust our readers have already discovered the error by the descriptions of the respective conditions in the text.

Another Antitoxin of Tuberculosis.—Dr. Maxutoff writes, in *Vratch*, that he has obtained from the blood of guinea-pigs with tuberculosis an antitoxin by which he has rendered other guinea-pigs immune.

Rokitansky's Sons.—The death of Rokitansky, the Viennese opera singer, at the age of sixty, and son of the celebrated Austrian pathologist, who also had a son a physician, recalls the answer given by Rokitansky, Sr., when asked what his sons did. He said: "*Der eine heilt und der andere heult*"—*i.e.*, "One heals and the other howls."—*Montreal Medical Journal.*

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending February 20, 1897: February 17th.—Surgeon R. Whiting placed on retired list, February 15th; Assistant Surgeon J. C. Rosenbleuth detached from the *Raleigh*, February 20th, and ordered to the *Massachusetts*.

The Brooklyn Medical Society.—At the annual meeting of this society, held January 15, 1897, the following officers were elected: *President*, Dr. F. G. Winter, 18 Patchen Avenue; *Vice-President*, Dr. Peter Scott; *Secretary*, Dr. B. F. M. Blake; *Corresponding Secretary*, Dr. J. H. Droge, 8 Stuyvesant Avenue; *Treasurer*, Dr. L. E. Meeker, 44 Linden Street; *Librarian*, Dr. Edwin A. Hatch.

A Curious Law in West Virginia.—Dr. Thomas R. Evans, of Charleston, W. Va., writes that, as the law now stands in that State, any physician or surgeon who "resorts to any expedient whatever" may be mulcted in heavy damages in case his patient dies, and yet he is not allowed to testify in his own behalf nor can another person testify for him. There is no stated time when such a suit can be outlawed. We could hardly credit the existence of such an unjust law did not our correspondent vouch for it. He states that a case in point has occurred, in which a medical man has been condemned to pay a fine of $10,000.

A Proposed National Sanatorium.—A bill has been introduced in Congress to give to the American Invalid Society, of Boston, the abandoned Fort Marcy Military Reservation in New Mexico, on condition that the society shall, within two years, establish on the reservation a sanatorium for the treatment of pulmonary diseases. This society is one organized to assist pulmonary invalids to go to the mountain region of the West for treatment.

Obituary Notes.—Dr. William S. Preston died at his home in Patchogue, Long Island, on February 16th. He was born in Ashton, Conn., in 1810, and went to Patchogue in 1837 and began the practice of

medicine. He was a member of the Suffolk County Medical Society. He was the first president of the board of education in Patchogue, and was an assemblyman from Suffolk County in 1854.—Dr. S. Gratz Moses, one of the oldest and most prominent physicians in St. Louis, died February 21st, aged eighty-five years. He was a native of Philadelphia, and received his medical education at the University of Pennsylvania, where he was graduated in 1835. He established the first dispensary in St. Louis many years ago, and was one of the founders of the Obstetrical and Gynecological Society.

The Plague.—The returns of the health authorities, made February 18th, report that since the outbreak of the plague there have been 6,853 cases and 5,447 deaths from the disease in the city of Bombay, and in the entire presidency, 9,911 cases and 8,006 deaths.

A Series of Coincidences.—The sixty-second double-wedding anniversary was recently celebrated, in a small town in Indiana, of Moses and Isaac Marty, twins, who married Tabitha and Lavinia McCormick, twins. Each couple has had seven sons and five daughters, the first children being born within a few days of each other, and the last children also being of almost exactly the same age.

School Physicians.—At a recent meeting of the board of education of this city the following were appointed school physicians for the present year: Drs. W. Gill Wylie, John G. Truax, Josephine Walter, Clement Cleveland, Alexander Lambert, A. M. Jacobus, Matthias Nicoll, Jr., John Rogers, Jr., P. J. Lynch, and Samuel M. Buckner.

Fees for Expert Testimony.—Judgments were entered recently against the city, in favor of Dr. Allen Fitch, Dr. Allan McLane Hamilton, and Dr. Graeme M. Hammond, for professional expert services rendered in the case of the People *vs.* Maria Barberi. The judgments are for $3,950, $1,500, and $1,800 respectively. No funds being available from which the district attorney might pay them, the doctors had to sue for their fees. Epileptic homicides are expensive luxuries in a community.

The Political Aspect of the Montreal Meeting.—At a dinner given recently in London to Dr. Roddick, of Montreal, president-elect of the British Medical Association, he touched in his speech upon the political significance of the meeting in August next. He said that he felt it was a great contract to bring the association to Montreal, but he was an imperialist, and if there was anything by means of which he could bring the premier colony of Canada closer to the British Isles he would be always willing to make use of it. There was no doubt that the Canadians had not always been looked after quite so well by their friends in Great Britain as they ought to have been; they had felt themselves neglected, and they had often had occasion to feel that the English did not know them as well as they ought, and as he wished they did. He hoped it would be many a day before Canadians added more stars and stripes to the flag of the United States, and that they would be satisfied for a long time with the flag that was wrapped around Wolfe on the Plains of Abraham and which later led Brock on to victory. He thought they were getting in the thin edge of the wedge of genuine imperialism in bringing over in the same year to Canada two great associations like the British Medical Association and the British Association for the Advancement of Science.

Widal's Typhoid Reaction.—Fränkel, of Halle, in the course of some experiments with Widal's test for typhoid fever, found the reaction present in the case of two men who were supposed to have had the disease a year before the examination. This is a point that might profitably be made the subject of further research, for if it is the case that the blood preserves the reaction for an indefinite period after recovery from the disease the test would lose much of its value in the case of hospital patients and others whose previous history cannot be certainly learned.

Influenza is rife in Baltimore, and the *Maryland Medical Journal* incriminates the abominable brick sidewalks of that city. These, it says, add greatly to the dampness of the atmosphere. "When the rains and snows are not wetting the bricks, the householder is allowing the servant to soak the bricks with water. Thus Baltimoreans have damp sidewalks a large part of the day. A reform in sidewalk paving and washing is needed in a city where lung troubles add so materially to the mortality."

More Medical Peers Wanted.— Sir Joseph Lister's elevation to the peerage is regarded by the editor of *The Practitioner* as not an honor to the profession of medicine alone. "It must be remembered," he says, "that Lord Lister is something more than a doctor. He is the highest official representative of science in this country, and it is not unlikely that his claims as the reformer of surgery might have been overlooked but for the lucky coincidence of his being the president of the Royal Society. It would be a graceful thing if, on the occasion of the Queen's 'diamond jubilee,' a coronet were given to one of the fathers of the church medical, such as Sir William Jenner or Sir James Paget, whom the profession could claim as wholly its own.

A Prosperous Practice.—For the year ending December 31, 1896, at the bureau of medical and surgical relief, out-door poor, Bellevue Hospital, 138,578 visits were made, of which 50,493 were from new patients. The number of prescriptions given was 159,060.

The Widening Ranks of the Medical Profession.—A proposed amendment to the medical practice law, recently introduced into the Missouri legislature, exempts from punishment for practising medicine or surgery without complying with the provisions of the act, all graduates of any "legally chartered and regularly conducted school of osteopathy." We have no idea what is the special absurdity advanced by the osteopaths, but as we understand there are some in New York the counsel of the County Medical Society might perhaps ascertain incidentally while looking into their qualifications.

Guarding Against Impure Ice.—The Paterson board of health has refused to permit the sale in that city of ice which has been cut from the Passaic River. For the last six years the ice dealers who have harvested their crops from the Passaic have held their permits without renewal. But the river has been found to be infested with typhoid bacilli, and the health authorities have declared the water unfit for ice harvesting. Accordingly, they have ordered all ice dealers to renew their applications for permits, and all those who procured their harvest from the Passaic have been refused renewals. The harvesting has gone on, however, and doubtless the companies will sell their ice somewhere, if not in Paterson, perhaps in New York.

Happy Kentucky.—At the annual banquet of the New York State Medical Society, during the recent meeting in Albany, Dr. J. M. Matthews, president of the State board of health of Kentucky, in response to the toast "sister societies," said that recent legislation in his State had rid the State completely of unqualified practitioners.

Lepers in Various Places.—The number of lepers in the Molokai colony is between 1,100 and 1,200, not 11,000 and 12,000, as was recently printed in an extract from a letter written by Dr. Mouritz, of Mapulehu. The number of lepers in Columbia has risen from 400 to 27,000, not 2,700, as was printed in a letter recently. There are some lepers in or around this city, but we cannot say how many, and we are disinclined to print any more leprosy statistics for the present, until the tendency of ciphers to displace themselves has been overcome.

Castration for Rape.—The house committee on public health of the Kansas legislature has made a favorable report on a bill which does away with a penitentiary sentence for men convicted of assaulting women and substitutes castration. The Social Purity League of Topeka has been urging the passage of this bill, and the leaders in the league claim enough votes in both houses to pass the law, and have secured the promise of Governor Leedy's signature. They say that, following the lead of Kansas, ten other States will have the same law at the next session of their legislatures.

A Chance for the Antivivisectionists.—If, instead of trying to retard the progress of true science, the antivivisection fanatics would take hold of a sensational preacher in Michigan, who kills cats in the pulpit, they might be of some use in the world. According to an account in the *Cleveland Leader*, it was announced that the Rev. W. L. Laufman, of Cadillac, Mich., assisted by Dr. C. E. Miller, would kill two cats in the pulpit of the Methodist church, to illustrate Laufman's sermon on tobacco on February 7th. On that day the church was packed. Prominent on the pulpit were packages of fine-cut and plug chewing-tobacco. Laufman contended in his sermon that tobacco in any form was bound to fill the user with nicotine and eventually produce death. Spain of today, he said, was not the chivalric Spain of Columbus' time, because of the prevalent use of tobacco. He commented, also, on the decadence of Turkey and France, due, of course, to the use of tobacco; but forgot to mention that Russia was making giant strides sociologically, intellectually, and politically, despite the almost universal use of tobacco. Then the cats were brought up by Dr. Miller. An assistant held them while the doctor administered the nicotine. The first one died in a minute and a half, while the attendant held it, after three drops of nicotine had been placed on its tongue. The next cat, a large one, received only two drops, the purpose being to illustrate the sickness and spasms which the first dose of tobacco creates. A second dose of two drops was given, and in a minute and a quarter the cat was dead. This humble follower of the Lord then announced that next Sunday he would kill some more cats, to show the effects of alcohol, and also have on exhibition the stomach of a drunkard.

Riotous Athenian Students.—The recent riot by medical students in the University of Athens originated in a rebuke addressed by one of the professors to some students who were creating a disturbance during the performance of an operation. The students considered themselves insulted, although the professor assured them that he had no intention of doing anything of the sort. They would not accept the explanation, but clamored for his resignation, and then, for some reason as yet unexplained, tried to break up the lectures in the law school. The law students, however, resented the interference, whereupon a free fight ensued. Then the police took a hand and made some arrests, but were stoned. Next the students tried to kill the librarian of the university. The troops were now called out, and the university was blockaded, but the students managed to get a supply of arms and provisions, and spent the night there. The next morning several hundred of them marched out, with the purpose of going to the palace, but ran up against the soldiers and police, and had a pitched battle with them. The rioters were finally subdued by the fire department, and after a while lectures were resumed at the university.

American Medical Editors' Association.—The next meeting of this association will be held in Philadelphia, during the session of the American Medical Association in June. Dr. Hobart A. Hare, of Philadelphia, is *President;* Dr. H. Bert Ellis, of Los Angeles, *Secretary*.

Philadelphia Pediatric Society.—At a stated meeting of the Philadelphia Pediatric Society, held on February 9th, Dr. J. P. Crozer Griffith presented two cases of unilateral tremor—one in a boy with hemiplegia, and the other (associated also with rotatory spasm of the head) in an infant, about twenty-two months old, without other obvious cause than nutritive defect. Dr. Howard S. Anders exhibited a beautiful skiagraph of a fœtus. Dr. Alfred Hand, Jr., demonstrated a girl, of about fourteen years, in whom recovery had ensued from an attack of cervical pachymen-

ingitis five years before. Dr. J. P. Crozer Griffith read a paper on Pasteurization of milk, and exhibited the Freeman Pasteurizer. Dr. C. H. Weber read the report of a case of noma in a child without recognized preceding infectious disease. Dr. J. H. McKee read a paper on enuresis, and Dr. J. F. Prendergast recommended the employment of the cold douche in treatment, as a result of the phenomenal success in ninety cases thus treated in a public institution, with recovery in eighty-four.

Philadelphia Museums.—Dr. William Pepper has been re-elected president of the Philadelphia museums.

Camden (N. J.) District Medical Society.—At a meeting of the Camden District Medical Society, on February 9th, Dr. B. S. Lewis read a paper on "Cretinism."

Medical Aid for Armenian Refugees.—Lady Henry Somerset has sent a woman physician and two nurses to attend to the medical wants of the women among the Armenian refugees in Bulgaria.

A City Ordinance Against Spitting.—It is reported in the papers that the municipal authorities of Phœnix, the capital city of Arizona, have passed an ordinance imposing a fine of $10 upon any one spitting on the sidewalk.

Alcoholism and Idiocy.—M. Bourneville has submitted to the Paris Public Health Society the following statistics, which show the influence of alcoholism in the production of idiocy. Of 1,000 idiotic, imbecile, backward, or epileptic children admitted to the Bicêtre Asylum between 1880 and 1890, 471 had drunken fathers, 84 had drunken mothers, while 65 were of alcoholic parentage on both sides. In only 209 cases was there no history of alcoholism on either side. In 175 no information on this point was forthcoming. In 57 cases it was positively ascertained that conception had taken place while the father was drunk, and in 24 other cases the same circumstance was extremely probable, though not quite certain.—*British Medical Journal.*

Helminthiasis Extraordinary.—The following medical item appeared in *The Boston Weekly News-Letter*, January 14, 1717, the first newspaper, and at that time the only one, published on this continent: "*Boston*, On the Lords day Morning the sixth Currant, a strange thing fell out here, One Thomas Smith a Sawyer about four Month ago, bought a Lusty Tall new negro, fit for his Employ, who after complain'd of something within him that made a Noise Chip, Chip, Chip; his Master sent for a Doctor, one Sebastian Henry Swetzer a German, who told him he had Worms, whereupon he gave him some Physick on Wednesday: from Thursday till the Lords Day he gave him some Powders, which on the Lords Day had that effect as to cause him to vomit up a long Worm, that Measur'd a hundred and twenty eight Foot, which the negro took to be his Guts; it was almost as big as ones little Finger, its Head was like a Snakes, and would receive a Mans little Finger into its Mouth, it was of a whitish Colour all full of Joynts, its tail was long and hard, and with a Microscope it seem'd to be hairy; the Negro before voiding the Worm had an extraordinary Stomach."—*Albany Medical Annals.*

Venereal Disease in the Indian Army.—Since the Indian government passed the "cantonments act," abandoning medical inspection of prostitutes visited by the soldiers, there has been an enormous increase in venereal disease among the troops. Out of seventy-three thousand British soldiers now in India, only twenty-four thousand are not suffering from a special disease more or less severely. One-half of the whole army is incapacitated from prolonged marching service. Preventive measures against the disease are taken in every army, and were found of the highest utility in the Indian force when medical inspection of the cantonments women was practised. The act abolishing inspection was passed under pressure from English religious societies. The viceroy's council has urged the repeal of this act, but this is violently opposed by many clergymen and religious associations in England.

The Prince of Wales' Hospital Fund.—The Prince of Wales has sent to the London papers a long communication, in which he announces the creation of a fund, to be called the Prince of Wales' Hospital Fund for London, to commemorate the sixtieth anniversary of the Queen's accession to the throne. The object is to secure about £150,000 annually by subscriptions of a shilling and upward to meet the needs of the hospitals which are not met by existing funds, with which the proposed fund is not intended to interfere. The communication states that a council will be appointed, of which the Prince of Wales will be president and Baron Rothschild treasurer. It might be possible to secure $750,000 this year while the people's feeling of loyalty and affection for the Queen is running high, but we question whether the collection could be repeated annually or whether enough could be raised now to establish an endowment fund of sufficient size to yield this income. The recipients of hospital charity in London are just at present rather dissatisfied with attending physicians and surgeons whose privilege it is to treat them for nothing. The patients think the doctors ought to pay for being allowed to see and prescribe for them.

The Best Way to Take Cold.—While all the world is sneezing and coughing with more or less grace and vigor, it is not surprising to find a large portion of the medical world agitated over the question as to the best way of taking cold, whether there is more chance of doing so by going from a warm to a cold atmosphere, or the reverse. In attempting to decide the question we are reminded of the report of the discussion of a debating society which we once saw in a country newspaper. It was as follows: "The question for discussion was: 'Who leads the happier life, the farmer or the inhabitant of the city?' The question was decided in the affirmative." We decide our question also in the affirmative.—*The Hahnemannian Monthly.*

Society Reports.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, February 15, 1897.

JOSEPH E. JANVRIN, M.D., PRESIDENT, IN THE CHAIR.

Inaugural Address.—DR. JANVRIN read a brief address on entering upon his second term of office, and spoke of matters which he thought had an important bearing upon the welfare of the association. His first effort during the past year had been to encourage scientific work. The result had been satisfactory, for the papers and discussions before the association had compared favorably with the work before other scientific bodies. Regarding the bylaws, a committee had been at work during the past year for their improvement, but he assumed that the changes proposed in its report in December had not been sweeping enough, since its acceptance was put off until the March meeting. He hoped the members who had any suggestions to make would communicate with the committee meanwhile. Regarding the directory, this had not been issued during the past year for want of funds. It might be continued by raising the dues from $2 a year to $3. The committee on hospitals and dispensaries had done important work during the year in trying to rectify the abuse of power by the commissioners of charities when they placed the appointment of physicians to public institutions in the hands of a few private corporations. A great wrong had been committed, and the president believed that no member of the medical profession, whether a member of the association or not, could take any other view of it. Unfortunately the scope of the work assigned this committee seemed not to have been fully understood by all members of the association. Yet its duties were plain, and consisted simply in doing whatever was possible to correct the abuse of power referred to. It had not gone beyond its authority in that respect, nor had it been influenced by friendship or personal feeling. The president hoped the association would carry on this work until a full recognition of the rights of the profession in the matter mentioned should crown its efforts. He wished to make one suggestion to the committee itself. He hoped it would, at as early a date as it could, turn its attention to the abuses existing in dispensaries and out-door departments of hospitals, whereby thousands of persons were being aided in becoming paupers and the younger members of the medical profession were being defrauded of fees which, though small, would assist them while building up a practice. He felt very strongly on this point, but he was always ready to take an active part in worthy charity. Believing, as he always had, that the code of ethics of the American Medical Association was the best itemized exponent of the golden rule for our guidance, and that in its essential features it could not be improved upon, he felt that physicians should accept it in good faith, try to live up to it, and endeavor to do their duty in enforcing it without fear or favor. When a difference of opinion arose in eminent bodies, and for any reason it seemed best for any member or members to resort to the press for the ventilation of their views or justification of their acts, they should remember that it was not to the secular press they should turn, but to the medical journals, whose pages were always open for free and impartial discussion of moot points. To resort to the secular press smacked of quackery, or showed the weakness of the cause of those who hoped thus to evoke public sympathy. "With malice toward none and charity for all, let us come together and settle our differences at once, and make this association the foremost one of the county in all work devoted to the honor and rights of the medical profession."

Special Meeting to Consider Hospital and Dispensary Abuse.—The president was handed a request signed by fifteen members to call a special meeting to consider the hospital and dispensary abuse. The president appointed Tuesday evening, February 23d.

Opticians' Bill Opposed.—DR. MANLEY offered resolutions opposing the bill before the legislature relating to the fitting of glasses by opticians. One resolution as adopted was: "*Resolved*, That the fitting of glasses to the eyes is practising medicine, and that in order to carry out the functions of the physician in this particular it is necessary that one should have that knowledge which can only be acquired by complying with the laws governing medical practice." Carried.

Board of Health and Tuberculosis.—The association was asked to adopt the spirit of some resolutions which had been adopted by the West Side German Dispensary, opposing the action of the board of health in placing tuberculosis among the communicable diseases, over which the board had almost arbitrary power. The resolutions also embodied the opinion that the health board ought not to take such important steps without first asking for and receiving the endorsement of the proposed action by the Academy of Medicine and the two county medical societies, for without the co-operation of the general profession the board's edicts must prove abortive.

After some discussion by DRS. WARDEN, MCLEOD, and MANLEY, DR. DENISON moved that action on the resolutions be postponed until the next meeting, and that the board of health be notified. Carried.

On motion of DR. GALLANT, a vote of thanks was extended by Dr. P. B. Porter for his long and active service as secretary.

Therapeutic Hints.

Cascarine.—This is recommended as a substitute for cascara sagrada in habitual constipation, in pills of one and a half grains, one to four being taken in the evening. The advantage of cascarine is that it acts with more certainty and without causing colic.—DR. SCHOENLAUB, *Schweiz. Woch. f. Chem.*

Asthma.—The "cigarettes Espic" are very widely used. Their formula, according to Trousseau, is as follows:

R	Fol. elect. herb. belladonnæ	0.36
	Fol. elect. herb. hyoscyami	0.18
	Fol. elect. herb. stramonii	0.18
	Fol. elect. phellandrii aquat	0.06
	Extract opii	0.008
	Aq. laurocerasi	q. s.

The leaves, well dried and freed of their ribs, are cut up and carefully mixed. The opium is dissolved in cherry-laurel water and the mass is uniformly dampened with the solution. The paper which is used in making the cigarettes is also previously washed in a maceration of the leaves above named in cherry-laurel water and carefully dried. The patient smokes one or two of such cigarettes during an attack.—*Twentieth Century Practice of Medicine*, p. 169, vol. vii.

Vasogene, a compound of a heavy hydrocarbon oil saturated with oxygen, may be combined with iodoform, etc., which it dissolves, for injecting tuberculous abscesses, fissures, etc.—*Pharmaceutical Journal.*

Dysmenorrhœa.—

℞ Antipyrini 10
Ammon. bromid.,
Potass. bromid. ..... āā 5
Ext. viburn. prun 20
Spir. vini gallici,
Syr. cort. aurant. ..... āā 40
Aq. dest. 90
M. S. Take a teaspoonful four or five times daily.

For treatment of dysmenorrhœa in young girls, the following may be found useful in controlling the pain:

℞ Tinct. belladonnæ fol. 5
Tinct. opii camphoratæ 10
M. S. Take fifteen drops in water as required.

—*Twentieth Century Practice of Medicine*, p. 587, vol. vii.

Pneumonia.—Very important drugs in the treatment of pneumonia are the four alkaloids—strychnine, cocaine, atropine, and caffeine—which act as stimulants to both circulation and respiration. As a cardiac stimulant and tonic, strychnine is inferior only to digitalis, and should always be used when there is exhaustion in pneumonia. Cocaine resembles strychnine in its cardiac action; atropine as a heart stimulant is decidedly inferior, but exceeds both strychnine and cocaine in its influence upon the vasomotor centres, and is, therefore, especially applicable to those cases in which collapse occurs or is threatened at a time of crisis, at which period its power of checking excessive sweating often gives it further advantage. Of these alkaloids atropine is probably the most active in increasing respiratory movements in the normal man, but it has less power in asserting itself in the face of opposition than has either strychnine or cocaine, and is therefore practically less available. Strychnine seems to be more active and efficient than cocaine, and does not, as does cocaine, produce cerebral excitement. Caffeine cannot be looked upon as a powerful respiratory stimulant, but affects decidedly the cerebral cortex, and therefore, if employed at all, must be used in small dose as an adjuvant, or in special cases when it is desired to overcome stupor.—Drs. Wood *and* Fitz, *The Practice of Medicine*, p. 752.

Castor-Oil Mixture.—

℞ Glycerini,
Olei ricini. ..... āā ʒ i.
Olei caryophylli. ..... gtt. iv.
M. S. Shake thoroughly. Tablespoonful contains dessertspoonful of castor oil.

If this mixture, after it is shaken to thorough homogeneity, be put into an ice-cold spoon or ice-cold water, it will congeal into a very thick mass which can be swallowed without disgust.—Drs. Wood *and* Fitz.

Metrorrhagia.—

℞ Ergotini,
Quininæ sulph. ..... āā gm. 4
Ext. hyoscyami,
Pulv. digital. fol. ..... āā gm. 0.40
M. et ft. pil. No. xl. S. Take from five to ten pills daily.

Menorrhagia with Dysmenorrhœa.—

℞ Ext. fluid. hydrastis canad.,
Ext. fluid. viburn. prun. ..... āā gm. 15
M. S. Ten drops every two hours in a little sugar and water.

—*Twentieth Century Practice of Medicine*, p. 579, vol. vii.

The Whale Cure for Rheumatism.—The following appears in the *Dublin Journal of Medical Science*, November, 1896: "It is reported that at the town of Eden, a place in Australia which stands on the shores of Twofold Bay, there is a hotel where rheumatic patients congregate. Whenever a whale has been taken the patients are rowed over to the works in which the animal is cut up, the whalers dig a narrow grave in the body, and in this the patient lies for two hours as in a Turkish bath, the decomposing blubber of the whale closing around his body and acting as a huge poultice. This is known as the 'whale cure for rheumatism.'"

Malakin, hitherto employed in rheumatism and to reduce fever, possesses decided anthelmintic and vermifuge properties.—Ottolenghi.

Creosote Pills.—

℞ Beechwood creosote ..... 10 gm.
Powdered liquorice root ..... 20 "
White of egg ..... 5 "
M. et div. in pil. No. c.

—Kathrein.

Hyperidrosis Pedum.—Apply with a brush for two or three days a solution of formalin (Höchst). If excoriations are present, they must be healed beforehand, and care must be exercised during the application not to breathe the fumes of the formalin.—Adler, *Prager med. Woch.*, No. 39.

Metrorrhagia.—

℞ Ergotininæ. ..... 0.20 cgm.
Alcoholis ..... 2. gm.
Aq. laurocerasi ..... 10. gm.
Aq. dest. ster., q. s. to make 100 gm. of solution.
S. Inject in twenty-four hours from a quarter to a half of a syringeful.

—*La Presse Médicale.*

Granulated Lids.—Paint the mucous membrane of the lids with a solution of pure iodine mixed with liquid vaseline (oleum petrolei) twice a day. In chronic cases use vaseline containing from a half to one per cent. of iodine. In about four days improvement begins, and in about twenty a cure is generally effected.—Neznamoff.

Scraped Apple is said to disguise the taste of quinine.

Hydrobromate of Hyoscine not only quiets the nervous symptoms and induces sleep but destroys in a measure the desire for alcohol.

Gonorrhœal Rheumatism.—The treatment of gonorrhœal rheumatism is very unsatisfactory. We have never found the salicylates, colchicum, the iodides, or the mercurials to exert a distinct influence for good. In the acute cases rest, fixation of the joints by splints, and blisters or the application of the thermo-cautery over the joints, constitute the major part of the treatment. In chronic cases careful attention to the general health, the best possible hygienic surroundings, the administration of tonics and of arsenic, and the use of massage and passive movements, comprise about all that can be done by the physician. The utmost importance should always be attached to the local treatment of the genito-urinary organs; the obstinacy of the disease often depends upon the existence of a slight chronic gleet. The surgical treatment of the inflamed joints, by opening and irrigation, is said to have yielded satisfactory results.—*The Practice of Medicine*, p. 70, by Drs. Woods *and* Fitz.

Calcium Chloride in dose of one to three grams is claimed by Savill to allay itching in a remarkable degree.

Functional Derangement of the Liver.—The bicycle surpasses calomel. It works like a charm also in all the sympathetic ailments which arise from too much acid in the system.—E. B. Turner.

Diabetes.—Some severe cases with rapid loss of weight may be kept back from the cachectic stage by the use of calcium.—Grube.

Persistent Diarrhœa of Phthisis.—

℞ Acid. sulph. dil.,
Nepenthe.....āā ♏ x.
Syrupi aurantii.....ʒ i.
M. Ex. aqua sumend.

—Nansome.

Dermatitis Roentgeni is often of too serious a nature to permit of the employment of *x*-rays in reckless therapeutic experiments.

Thyroid Preparations are looked upon as practically useless in skin affections by Zaroubine (*Vratch*, Nos. 25 and 26), and, besides, anæmia and cardiac affections present formal contraindications to their use.

To Abort Coryza.—

℞ Phenic acid, pure,
Spirits of ammonia.....āā 5 gm.
Alcohol at 90 per cent..... 10 "
Distilled water..... 15 "
S. Gtt. x. on blotting-paper to inhale every hour.

—Lermoyez.

Chestnuts.—Ten drops of tincture of horsechestnuts in sweetened water before meals, morning and night, not only stops the pain but is curative in hemorrhoids (twenty-one cases).—Astault.

Sand Baths, artificially heated, offer an excellent means of inducing perspiration, exciting the functions of the skin, etc. They are useful in rheumatism and have no bad effect upon heart or circulation.—Besrodnoff.

Vermicide.—

℞ Distilled peppermint water..... 50 gm.
Ethereal extract of malefern..... 6 "
Essence of turpentine..... 1 "
Syrup of orange flowers..... 30 "
To take at one dose.

—Comby.

Appendicitis.—Catarrhal conditions are amenable to medical treatment at the commencement when the symptoms are not very urgent. Resection of the appendix is indicated when the attacks are frequently repeated and the iliac fossa remains swollen in the intervals of the attacks, and, above all, if the presence of pus around the appendix is suspected. It is better to operate between two attacks.—Wolff.

Malaria, in a case which would not improve under quinine and arsenic, presenting marked cachexia, etc., rapidly improved under methylene blue in doses of twenty-five centigrams three times daily.—*La Méd. Mod.*, September 13th.

Thrush.—No washing out of the mouth. Good hygienic conditions as prophylaxis. In case of epidemic or endemic, application of silver solution, three per cent.; as prophylactic application, one per cent.—Grosz.

Night Sweats of phthisis are diminished and sometimes made to disappear by the employment of sulfonal in dose of one to two grams.

Tuberculous Meningitis.—

℞ Sodii iodidi..... ʒ iiss.
Syr. aurantii..... ℥ ij.
Aq..... ʒ x.
Two tablespoonfuls the first day, four the second, six the third, and eight thereafter.

Every second day give ten grains of calomel in two doses. Apply a blister to each leg, then to each arm, and finally to the nape of the neck. Rub the shaven head with equal parts of croton and olive oil. Give milk and champagne.—*Medical Press*, October 21st.

Herpes Zoster.—I wish to call attention to two valuable (internal) remedies for this condition, viz., cubeba and rhus toxicodendron. The former, if painless and quite recent; the latter, if older and painful.—John C. Morgan, M.D.

Tetany.—In the treatment of tetany the two indications are to favor the expulsion of the toxic substances and to prevent their formation. Both indications are met by calomel, which Oddo recommends to be given every other day in doses of three-fourths grain or more, according to the age of the child. Washing out the stomach is a useful measure, which, however, must be adopted with discrimination, owing to the risk of exciting laryngeal spasm.—*British Medical Journal.*

Delirium Tremens.—

℞ Potass. bromid.,
Sodii bromid.....āā gr. xv.
Chloral. hydrat..... gr. x.
Tinct. zingiberis..... ʒ x.
Tinct. capsici..... ʒ v.
Spirit. ammon. aromat..... ʒ i.
Aquæ..... ʒ ij.
M. S. Dose: A tablespoonful.

— *Vanderbilt Clinic.*

Neurasthenia.—Dr. Neff summarizes his paper in the *Physician and Surgeon*, October, 1896, as follows: (1) Neurasthenia is a nervous disease having distinctive features and well-marked diagnostic signs. (2) Neurasthenia may be the outcome of various other functional and organic affections; therefore it is divisible into two forms—(*a*) simple neurasthenia and (*b*) symptomatic neurasthenia. (3) The symptoms of neurasthenia are dependent on nervous exhaustion. Experimental physiology would indicate that this is coincident with changes in the nerve cell induced by fatigue. (4) The etiology of neurasthenia is divided into predisposing and exciting elements. In the former, heredity has an important rôle, the prominent exciting cause in the latter being fatigue. (5) The prognosis in the uncomplicated form is good. In the so-called "degenerative form" and in elderly persons relapses are frequent. (6) The treatment of neurasthenia has as an essential feature the employment of rest in some form, associated in some cases with dietetic, electric, and hydropathic treatment, and the use of appropriate drugs to combat symptoms.

Acute Rheumatism.—Dr. Bishop says: "The mistake usually made in the administration of alkalies is in ordering too definite an amount. I have seen a great many cases of articular rheumatism treated according to a regular formula. It was a mixture of citrate of potassium and acetate of potassium, of which a certain number of grains were given at certain intervals. This is not the best way of giving alkalies. It is much better to lay in a good supply of bicarbonate of sodium, and give this persistently in drachm doses as often as practicable, until the urine becomes alkaline. We can give other alkalies in combination if we wish, but the main point to remember is the importance of influencing the reaction of the urine. Bicarbonate of sodium is so familiar a substance that it is easy to get the patient to take a sufficient amount."

Catarrhal Jaundice.—This catarrhal or simple jaundice results from the following causes: (1) Duodenal catarrh, in whatever way produced, most commonly following an attack of indigestion. It is most frequently met with in young persons, but may occur at any age, and may follow not only errors in diet, but also cold, exposure, and malaria, as well as the conditions associated with portal obstruction, chronic heart disease, and Bright's disease. (2) Emotional

disturbances may be followed by jaundice, which is believed to be due to catarrhal swelling. Cases of this kind are rare and the anatomical condition is unknown. (3) Simple or catarrhal jaundice may occur in epidemic form. (4) Catarrhal jaundice is occasionally seen in the infectious fevers, such as pneumonia and typhoid fever.—*The Principles and Practice of Medicine*, by William Osler, p. 430.

Dysmenorrhœa.—

℞ Phosphori. . . . . gr. $\frac{1}{10}$.
Ferri valerianat. . . . . gr. i.
Zinci valerianat. . . . . gr. i.
Quin. sulph. . . . . gr. i.
Ext. aloes . . . . . gr. i.
S. One such pill to be taken three times a day.

Also:

℞ Tinct. cannabis ind. . . . . ♏ x.
Syr. chloral. hydrat. . . . . ♏ xx.
Glycerin . . . . . ʒ i.
Aq camphor. . . . . ad ℥ i.
For one dose.

This should be taken as soon as the pains commence and may be repeated in three hours; it is well to give only two doses in any given twenty-four hours, as many women show signs of considerable excitement, with giddiness and delirium, after repeated doses of Indian hemp.—Bedford Fenwick, *Medical Times and Hospital Gazette*.

Hysteria.—Of predisposing causes, two are important, heredity and education. The former acts by endowing the child with a mobile, abnormally sensitive nervous organization. We see cases most frequently in families with marked neuropathic tendencies, the members of which have suffered from neuroses of various sorts. Education at home too often fails to inculcate habits of self-control. A child grows to girlhood with an entirely erroneous idea of her relation to others, accustomed to have every whim gratified, and abundant sympathy lavished on every woe, however trifling. She reaches womanhood with a moral organization unfitted to withstand the cares and worries of every-day life. At school, between the ages of twelve and fifteen, the most important period of her life, when the vital energies are absorbed in the rapid development of the body, she is often cramming for examinations and cooped in close schoolrooms for six or eight hours daily. The result is too frequently an active, bright mind in an enfeebled body, ill adapted to subserve the functions for which it was framed, easily disordered, and prone to react abnormally to the ordinary stimuli of life.—William Osler, *The Principles and Practice of Medicine*, p. 967.

Extra-Uterine Pregnancy.—Dr. L. B. Frankenthal (*American Gynecological and Obstetrical Journal*) gives from his personal experience of thirty-seven cases the following summary: 1. Impregnation occurs in the tube. 2. In the majority of cases the etiology of extra-uterine pregnancy can be established by a mechanical hindrance to the wandering of the fecundated ovum from the tube to the uterine cavity. 3. Treat conservatively only those cases seen some time after primary rupture, in which you feel fairly certain of the death of the fœtus, in which the alarming symptoms have subsided, and in which presumably absorption is going on. 4. Operate early for reasons given above. 5. The operation during shock is not contraindicated, for frequently just the removal of the foreign body from the peritoneal cavity stops shock. 6. Drainage, preferably vaginal, should be done in all cases. 7. To relieve shock, transfuse salt solution when the amount of blood lost is not too great and when the hemorrhage has not occurred repeatedly at long intervals; for then direct transfusion should be practised, as the functions of vital organs have become impaired and they need more than a mechanical stimulus—they need red blood corpuscles. 8. To hasten some operations merely clamp the adnexa and leave clamps *in situ*. 9. Whenever possible remove the placenta; if not, tampon and drain. 10. In deciding when to operate after viability, do not consider the child, for not only are they short-lived (of fifty-seven cases collected by Harris five only were alive after two years) but likewise such children are deficient in development. 11. Sterility on account of the number of criminal abortions and prevention of conception is not a very reliable symptom.

Hæmoptysis.—Dr. Capitan (*La France Médicale*, September 25, 1896) advises as follows: If large quantities of blood are being lost, we may treat the symptom first and make an accurate diagnosis afterward. Place the patient in a quiet position with the head raised, and forbid movement. Place mustard plasters upon the lower extremities. Give pieces of ice to suck, and, if it is possible, a teaspoonful of ether in a little sweetened water. Above all, give a hypodermic injection, deep into the muscle by preference, of the following solution:

℞ Ergotin (Yvon) . . . . . 5 gm.
Morphine chlorhydr. . . . . 0.04 cgm.
Antipyrin . . . . . 1.50 gm.
Sparteine sulph. . . . . 0.20 cgm.
Atropine sulph. . . . . 0.002 mgm.
Aq. dest. . . . . q.s ut ft sol. 10 c.c.

A syringeful of this may be repeated every half or quarter hour until four or five have been given. If the patient can drink, a dessertspoonful of the following is given every hour or every half-hour:

℞ Ergotin (Bonjean). . . . . 2 gm.
Acidi gallici. . . . . 0.5 dgm.
Syr. terebinthinæ . . . . . 120 gm.

Acute Anterior Poliomyelitis.—Dr. Courtney (*Boston Medical and Surgical Journal*, December 17, 1896) speaks of its treatment as follows: "As the large majority of patients is seen by the family physician at the onset, he should, in directing his treatment, keep constantly in mind the fact that the lesion is primarily a vascular one, and do his utmost to limit the inflammation and preserve the integrity of the nervous structures by the use of counter-irritants and vasoconstrictors. For this purpose the child should be kept in a quiet room, and small doses of some antipyretic, together with bromide and ergot, are to be given. Locally, cold applications and mild counter-irritants over the affected portion of the spine are indicated. The child should be carefully fed, and the bowels thoroughly purged by the use of small doses of calomel."

Quinine is distinctly contraindicated in inflammation of the middle ear, of the skin, of the meninges, of the urinary and alimentary tract.

Rheumatism.—This is recommended as an agreeable salicylate mixture:

℞ Potassii acetatis . . . . . ʒ ij.
Acidi salicylatis . . . . . ʒ ss.
Syrupi limonis. . . . . ʒ ij.
Aq. menth. pip. . . . . ʒ viij.
S. Tablespoonful every three hours.
—*North American Practitioner*.

Phthisis.—Dr. Warburton Begbie gives the following as a sedative and tonic in cases of phthisis. It contains no opium.

℞ Acid. hydrocyan. dil. . . . . ʒ ss.
Acid. nitric. dil. . . . . ʒ iij.
Glycerini. . . . . ʒ i.
Inf. quassiæ. . . . . q.s. ad ℥ vi.
Ft. mist. S. A tablespoonful in a wineglass of water three times a day.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DEATH OF SIR SPENCER WELLS—HOSPITAL REFORM MEETING—ARMY AND NAVY MEDICAL REPORTS—SURGERY IN TYPHOID—HEMORRHAGE INTO PERICARDIUM—LIGATURE OF FEMORAL ARTERY FOR ELEPHANTIASIS—ANOTHER OPERATION FOR VESICO-VAGINAL FISTULA—TWO LAPAROTOMIES ON ONE PATIENT—SMOKING.

LONDON, February 5, 1897.

ANOTHER of our leaders has gone on to the majority. Sir Spencer Wells died at Antibes on Sunday night. He went there some weeks ago in fair health considering his state, for he was known to be failing for two or three years. He was within three days of his seventy-ninth birthday when an apoplectic seizure terminated his life in about twelve hours. The body will be brought to England for cremation, of which he was an ardent advocate. Soon after taking his M.R.C.S. he entered the navy and served some six years. He returned to his country's service on the outbreak of the Crimean war, the surgeoncy of the Samaritan Hospital being kept open for him. When he came back he took up there what may be called his life work, and after no slight anxiety and many disappointments on his part the hospital became the Mecca of ovariotomists. He was much indebted to Baker Brown, who had preceded him in this work and whose brilliant operations did so much to establish ovariotomy among recognized operations. After Brown's death Wells stood almost alone as operator, and his great successes brought him an enviable fame and position. He was president of the College of Surgeons in 1882. He was made a baronet in the following year. He leaves six daughters and one son, who takes the title. He was for some years editor of the *Medical Times and Gazette*—now defunct—in which his early cases were fully described. It is superfluous to refer to his larger literary efforts, which are well known to your readers, and are mostly the results of his personal experience. He was a genial gentleman, given to hospitality, and an excellent companion. He was most careful and painstaking in his work, thinking nothing too minute to deserve attention and regarding difficulties as to be overcome.

The Hospital Reform Association is making good play. Last evening this youthful organization held another meeting at St. Martin's Town Hall. Urgent as the subject of hospital abuse is, the very obviousness and universality of it makes attack seem almost hopeless. In presence of such obstacles professional apathy is apt to deepen. All honor, therefore, to the energetic few who are determined to rouse us. The resolution on the out-patient and casualty departments was an emphatic condemnation expressed in moderate terms. It was moved by Dr. Isambard Owen and seconded by Dr. F. J. Smith. Dr. Owen said that, allowing for many patients being reckoned more than once, some five hundred thousand received during the past year out-door relief from the great hospitals of London, and if to them be added the number treated at the smaller hospitals the total figures would be appalling. The legitimate field for charity is large enough, but it does not include those able to pay doctors out of their own pockets, and the administration of the hospitals at present is a gross injustice to those who are practising among the poorer classes. It is a fact, he declared, that many a doctor, both in London and the provinces, has been unable to earn his livelihood, because institutions founded for the benefit of those who cannot pay for medical aid are abused by those who can. The resolution on the subject was carried, as were others, agreeing to put the recommendations of the society before the governing bodies of the hospitals, and asking all who take an interest in our hospitals and charities to support the association.

The report of the army medical department for 1895 has now appeared. The ratio of sickness and mortality at home was not quite so good as in the previous year, but was still below the average. In the colonies as a whole, the health of the troops was below the standard of 1894, but in India there was a decline in the sick rate, though not sufficient to reach the average ratio. The naval report has also been issued for the same period and is satisfactory. The ratio of invaliding was 25.26 per 1,000. This is lower with one exception than any year since 1858, in which the present form of statistics began. Forty-eight lives were lost by the foundering of a pinnace, which somewhat raises the actual number of deaths, but of course drowning is a sailor's risk.

Perforation in typhoid fever has always been looked upon as fatal, but there is really a possibility of recovery, and the propriety of operative interference has often been considered since the modern advance of abdominal surgery. Two cases were brought before the last meeting of the Medico-Chirurgical Society that afford much food for reflection. The first was under Dr. Brunton and Mr. Bowlby. During convalescence the perforation occurred; the abdomen was opened and an ulcer the size of a small pea found after careful search. The ulcer occupied the centre of a Peyer's patch and had perforated the bowel. Ten sutures were used, extending to about an inch and a half along the long axis. Then flatus and fluid were allowed to pass into the coil, and there was no leakage while the lumen was free. Irrigation with hot water was employed and a drainage tube passed. The patient made a good recovery. I believe this is the first such result in England. Two other subjects died. Dr. Abbe's review of all recorded cases in your pages (January 5, 1895) was referred to at the society as complete. The second case brought forward at the same meeting was only one of supposed perforation, but on operation no lesion could be found. The symptoms usually associated with perforation were present, and as the patient was in good condition it was determined to operate as the only chance. The patient made an uneventful recovery. Dr. Norman Moore gave the society some important statistics showing that usually the perforation is within five feet of the cæcum—in three-fourths of the autopsies within three feet. In only one out of twenty-one cases was the perforation in the colon. Perforation was frequently later than commonly supposed—from the twenty-eighth to the forty-first day. He had never seen appearances to induce belief in complete repair, though peritonitis without perforation is common in enteric fever over the ulcerated parts of the intestine. Dr. S. Phillips remarked as to these two cases the symptoms resembled more closely those of perforation in the case in which it had not occurred, showing the extreme difficulty of diagnosis. Dr. F. Hawkins read an account of a case of jaundice with perforation of the gall bladder in the course of typhoid fever. Jaundice is a sufficiently rare occurrence in typhoid to give interest to a case without the addition of perforation of the gall bladder, but there was also pulmonary trouble by which death was hastened.

Among the cases exhibited before the Clinical Society was one of hemorrhage into the pericardium caused by a kick on the sternum at football. The patient, aged twenty years, went on playing for twenty minutes, but on going home became collapsed. Mr. Moullin incised the pericardium and inserted a drain-

age tube through which some six pints of blood escaped in the first three hours, clotting in the basin firmly. The tube was removed the next day and the patient sat up. He is well and has resumed football. Different from the burned child!

There was a case in which the femoral artery had been ligatured for elephantiasis and some remarks were made as to whether real benefit is likely to follow operations of this kind. One case was mentioned which is figured in Bryant's "Surgery."

At the Medical Society meeting there was present a man, aged sixty-four years, who had undergone resection of a stricture of the sigmoid flexure, the ends of the intestine being joined over a large bone bobbin.

Mr. Stanmore Bishop described a new operation for vesico-vaginal fistula, which seems ingenious but apparently must leave an inverted scar in the bladder, which would be likely to lead to phosphatic deposits. But Mr. Bishop said the scar was not at all rough, but practically enclosed in mucous membrane.

A case of two laparotomies in one patient, a woman, aged forty-five years, was related by Mr. Turner, who answered several questions as to the case.

Some of the members of the Harveian Society have lately been trying to persuade the others to permit smoking at the meetings. Last evening the proposal was put to vote and lost. A good thing, too, exclaims a non-smoker, and I am disposed to agree with him. I like my cigar at suitable times, but am not so devoted to the indulgence as to desire a roomful of smoke in debating medical questions. I hear that one suburban society permits smoking at its meetings.

OUR BERLIN LETTER.

(From our Special Correspondent.)

HEITZMANN—DEATH OF A PHYSICIAN BY CHLOROFORM—STRANGE ACTION OF DIPHTHERITIC SERUM—PEOPLE WITH TWO HEARTS AND THREE KIDNEYS—THE FRICTION STETHOSCOPE—EARLY DIAGNOSIS OF CANCER OF STOMACH—VIDAL'S TYPHOID REACTION—TABES DORSALIS IN CHILDREN—THE PEST CONFERENCE.

BERLIN, February 1, 1897.

ANOTHER widely celebrated scientific worker, Carl Heitzmann, has been called away from his labors by death. The name is well known to Americans especially, because of the many years he passed in New York as a teacher of microscopical anatomy in various medical schools. He was the author of the famous "Heitzmann's Anatomical Atlas," which has been used as a standard text-book by students of many countries, for several generations past and present. Although born in Vienna, unfortunately he could not obtain a university position in either his native country or Germany, and therefore emigrated to the United States, which he soon learned to regard as a second home. Ill, he returned to the land of his birth, where he remained until death ended his wanderings.

An instance of death from chloroform narcosis in Berlin, recently, affects the medical world in a peculiarly painful manner. A practising physician of that city was about to be operated upon for hemorrhoids. He was but a few seconds under chloroform when he collapsed, and in spite of all efforts to rescue him died on the table in a few seconds. Such a sad incident occurring within our own ranks warns us to be even more careful than heretofore in the selection and administration of an anæsthetic. It impresses upon us the value of local anæsthesia, the Schleich infiltration method, and it were well that physicians and surgeons became fully acquainted with this excellent procedure. Its universal adoption would reduce the total number of general anæsthesias at least one-half.

A peculiarly unpleasant result following the use of the diphtheria antitoxin upon his own person has been the experience of another Berlin physician, and has been a fruitful source for discussion between the friends and antagonists of the orrhotherapy. This gentleman had been treating a number of diphtheria patients, and became himself infected. Under all aseptic precautions he injected himself in the chest with the antitoxin. Soon there appeared a succession of abscesses starting from the point of injection. No sooner was one healed than a new one appeared in the immediate neighborhood, making life indeed quite miserable for the poor man. He demonstrated himself at a meeting of the Berliner medicinische Gesellschaft, relating his history and showing his abscesses, etc., and blaming the antitoxin as the cause of all his woe. At first he thought he had inoculated himself with the bacillus mallei (glanders), but Virchow found no such germ in the pus. A lively discussion was waged as to whether or not the antitoxin was the real cause of his condition. Of course it cannot be proven that it was not, but it evidently appears to be a case of staphylococcus inoculation, such as is also observed at times in ordinary hypodermic injections of morphine and other medicines. At all events it is to be regarded as a very rare sequence or complication.

Indeed we had opportunity to witness several rarities at the last meetings of the Berliner medicinische Gesellschaft. Dr. Hausemann, the pathologist, demonstrated the urinary organs of a male patient who had died of the perforation of an ulcer of the stomach. There were three complete and separate kidneys. The right kidney was entirely normal, but on the left side were two small kidneys, well formed and having each a separate pelvis but a common ureter. Such a double kidney is a very great rarity. Hausemann stated that he had only once before seen anything like the specimen he demonstrated. It was a pig which had four kidneys. He also showed a specimen of a heart which he claimed was a unicum, and which consisted of a normal-sized heart with a completely separated left auricle. The patient was twenty-two years of age. Upon opening the pericardium at the autopsy, it appeared at first as though there were two hearts; in addition to the apparently normal heart was a second sac filled with blood. The latter, which was larger than the real heart, represented the left auricle, and was entirely free from any muscular tissue. All the valves were intact and the foramen ovale was closed. Hausemann could find no cause for this abnormality.

At the same meeting Senator demonstrated a stethoscope devised by Aufrecht and constructed upon friction principles, very similar to those of the phonendoscope, detailed to you in a previous letter. It is a modification of the well-known "Schlauchstethoscope." At one end the tube is widened out into a small funnel, which is placed against the chest. The other end is shaped into an ear piece. In using the instrument the ear attachment is held in the ear while the funnel end is rubbed over the skin; strikingly appreciable changes in sound are heard. It is very useful in mapping out the heart. The boundaries of that organ can be sharply determined, and as obtained by this method differ very much from those gained by palpatory percussion corresponding to the real outline of the heart. The originator, Aufrecht, calls this instrument a metroscope, but Senator suggests the name of friction stethoscope, in order to exclude any possible confusion the term metroscope might cause.

At a meeting of the Verein für innere Medicin, Dr. Boas, the well-known specialist for stomach and intestinal diseases, showed a man, fifty-six years of age, upon whom an early diagnosis of cancer of the pylorus

was made from presence of lactic acid in the stomach, and upon whom a total extirpation with brilliant results was possible. Before the operation no tumor could be felt through the abdominal wall, notwithstanding repeated examinations. The operation was performed in June, 1896, and the patient to-day feels well, has gained thirty-one pounds in weight, and appears to be in good condition. Boas says: "If the empty stomach in the morning constantly contain remains of food of the previous day, and if we find lactic acid invariably present, and in addition numerous thread bacilli, we can almost positively diagnose the case as one of pylorus carcinoma. We are rapidly approaching the position in which we can with certainty diagnose a cancer of the stomach before it is palpable through the abdominal wall." The case in point well illustrates the great diagnostic advantage which Boas' discovery has given to these classes of cases.

At the same meeting the Vidal typhoid reaction was discussed with great interest. This reaction is as follows: Ten drops of serum of the blood of a typhoid suspect are mixed with typhoid bacilli, and placed under the microscope. If the case be really one of typhoid, the bacteria will be seen in heaps, "pasted together," with clear spaces between the several heaps; on the other hand, should the case not be a typhoid, the bacilli will be seen moving freely in the serum. A. Fraenkel, Stadelmann, Kirstein, and others testified to the positive value of the Vidal reaction.

As a curiosity I cite a case of tabes dorsalis in a boy, thirteen years of age, whom Dr. Bloch showed to the Gesellschaft für Psychiatrie und Nervenheilkunde. The father of the boy had lues and transmitted it to all of his children, all of whom, with the exception of the patient, were cured by a course of inunctions. In the fifth year of life he had dilatation of his pupils; gradually there developed incontinentia urinæ, fixity of the pupil, Romberg symptom, and absence of the patellar reflex. At thirteen years of age he presented all the clinical symptoms of tabes.

A question of lively interest, not only to Berlin but to Europe—yes, even to the entire world, is the combating of the bubonic plague and the prevention of its spread to other countries. Recently a conference was held at the Imperial Department of Health (kaiserlichen Gesundheitsamt) to discuss the advisability of ordering a quarantine against India. The plague will also be the topic for discussion at an international conference to be held in Venice on February 10th. It is almost certain that the German government will send a commission to Bombay to investigate the plague. The commission will be composed of sanitary and bacteriological specialists, and it is most probable that Professor Koch (now in South Africa investigating the rinderpest) will be at its head. It is to be hoped that the plague can be confined to India, for were it to gain a foothold in Europe it would be a matter of vital importance to America.

A BILL TO REGULATE OPTOMETRY.

To the Editor of the Medical Record.

Sir: A bill has been introduced in the legislature, known as assembly bill No. 459, entitled "An Act to Regulate the Practice of Optometry in the State of New York," which decrees that the regents shall appoint a board of examiners to examine any person who desires to treat any condition of the eyes requiring glasses, and grant a certificate of proficiency, which must be hung in a conspicuous place in the office of the recipient. The opticians who call themselves refracting opticians are behind this measure, and contend that the refraction of the eye is no part of medicine, and that physicians have no right to take unto themselves the exclusive privilege of this department.

Every physician must be fully aware of the evil consequences that will of necessity follow the passage of a measure of this kind, as the examination requires simply a knowledge of optics, and is one that any person can prepare himself for in a very short time. The sponsors of this measure claim that they need protection; that they have been fitting glasses for a long time, and that they have a right to continue to do so. In answer, we say that the time was, and not long ago, when the pulling of teeth, blood letting, and many of the functions of the physician or those having a medical education, were in the hands of the barbers; but increasing education has demonstrated that in order to protect the public, medical privileges, of which the fitting of glasses is one, can be safely entrusted only to those who by careful medical training are capable of discriminating between health and disease.

The present standard of medical education is higher in the State of New York than anywhere in the United States, and we urge the members of the profession to keep it so. If every physician who reads this statement will write to his or her representatives in the senate and assembly, protesting against the passage of assembly bill No. 459 in any form which obviates a medical education, as something which would be extremely dangerous to the public, the defeat of this measure is assured.

The committee on legislation would be happy to furnish names of representatives or any desired information.

CROOKES TUBES AND STATIC MACHINES.

To the Editor of the Medical Record.

Sir: That there are many physicians interested in the subject of my recent article on Crookes tubes is proved by the number of letters reaching me. If writers who have static machines and desire further information as to how to use them will enclose stamps, I will reply to all inquiries. It is certainly to be hoped that tubes will still further improve, but as long ago as the 20th of last September I was able to produce an excellent negative, fourteen by seventeen, of metallic objects through the trunk of a fully clothed adult, in five minutes' exposure, with the tube thirteen inches in front of the person's chest. It is worth while for physicians to know that similar work is within reach of them all, and I teach my students to do the same. With a fair tube it is a matter of skilled manipulation, which any one can learn. I speak of this because the authors of an *x*-ray paper recently read before the Franklin Institute exploit coils as the best way to excite Crookes tubes, and say: "We have very carefully investigated every claim to quicker exposures than these (thirty minutes for the trunk, at twelve to fifteen inches), often by a personal visit, sometimes by correspondence with personal friends whose reliability was undoubted. We have been unable to learn of any results equally good having been obtained in shorter times by any one, at any place, with any form of apparatus, and we do not believe any such have been obtained."

This seems to be conclusive proof of the inferiority of coils. There are probably five hundred physicians in the United States who already possess an electrical

machine that will do far better work, and all they need is to acquire the technique and proper tubes. I am continually demonstrating to my classes the accuracy of the above statements.

HOMING PIGEONS IN MEDICAL PRACTICE.

To the Editor of the Medical Record.

Sir: The note concerning "Homing Pigeons in Medical Practice," in your issue for January 30, 1897, has called forth a number of queries from medical men in different parts of the country, and it may be that an answer to some of them in your columns would interest other of your readers. Carrier pigeons are not the ones that carry messages, but are bred for show points exclusively, while the "homer" is bred entirely for work. Therefore the size of the "wart on the nose" is of no consequence to the homer, while it would be to the carrier. "A good horse is never of a bad color," so with the homer there is no standard for size, color, or shape; still, it happens that there is a pretty well-recognized type belonging to the best birds. They are of a composite breed, having received blood from several different sources—the "Cumulet," a pearl-eyed pigeon of the tumbler species, inclined to fly very high and long; the "Smerl," a round-headed small bird, somewhat like an owl pigeon, noted for its swift flight; and the "Dragoon," a strong robust pigeon, being the most prominent ancestors of the present day "Belgian homer." The colors most prevalent are blue, blue checkered, and red checkered. These are preferred to the solid white or black, as being less conspicuous marks for the hawk or gun. Many different names have been applied to these birds, but the one here used is most favored, as being the one best descriptive of the bird's effort. It is the bird's love of home and his endeavor to reach it that we utilize for our benefit. In establishing a loft of these feathered messengers, it is best to begin with a few pairs of breeders, which should be kept confined to the loft, with an outside covered aviary if possible, to give them access to the ground. If allowed their liberty they are almost sure to take French leave, no matter how long they have been confined. The young birds should not be trained till the age of four months, when they may be taken on successive days a mile or two from home in different directions; the distances may be increased in geometrical ratio up to one hundred or two hundred miles for birds in their first season's work. During the second season it is no unusual thing for birds to return from five hundred miles or a little more between daylight and dark. When the bird enters his loft it should be through bolting wires which open inward, allowing entrance but preventing exit. There are many devices for carrying messages safely, but in actual practice the one I really oftenest adopt is to have the message written on a prescription blank, folded into a strip about one inch wide, rolled around the bird's leg and fastened with a rubber band. When any of the birds are expected home, a cage should be set in the loft, into which the bird passes from the bolting wires. After his message is removed he may be released and the cage set for the next arrival.

The advantages to a practitioner in the rural districts from the use of this method of messenger service can hardly be overestimated. Take, for example, the young wife living remote from neighbors and expecting her confinement. By leaving two or three birds with her, she has the comforting assurance that she can send word to her physician at the rate of a mile a minute, so that, even before a human messenger could reach the office, the doctor, if at home when the bird arrived, could be ready to start. The bolting wires when pushed may complete an electric circuit which rings a bell in the residence, thus announcing the bird's arrival. During stormy weather or when the roads are almost impassable, it is quite a relief to get daily bulletins from the bedside which it may be almost impossible to reach.

As an instance of the grit and power of the true homer, I will mention the performance of a red-checkered cock bird, which made his escape from me in 1890, after being a prisoner for three weeks, with one wing plucked. The feathers had just begun to sprout, so that he could not fly more than a few hundred feet: yet in two weeks' time he returned to New York City, three hundred and twenty miles away, where he was recognized by his former owner, who wrote me of his arrival, not knowing that he had escaped. He was returned to me, kept prisoner from January, 1891, till September of the same year, during which he mated and raised two pairs of young ones, when he again escaped at 9 A.M., and was in New York the afternoon of the same day. Charles L. Lang, M.D.

Meriden, N. Y., February 13, 1897.

MEDICAL EXPERT TESTIMONY.

To the Editor of the Medical Record.

Sir: I notice with satisfaction that the Society of Medical Jurisprudence has taken into consideration the subject of expert medical testimony in courts of justice, with a view to securing a better condition of things than exists at present. That there should be some radical change in the method of securing expert testimony must be apparent to every reader of the Medical Record.

At present the function of the so-called medical expert would seem to be to throw dust in the eyes of the court and jury. He is generally called to bolster up a theory invented by some ingenious (and often unscrupulous) criminal lawyer, and he generally tells only as much of the truth as will bear favorably upon his side of the case—the side upon which the retainer lies. He becomes, consciously or unconsciously, the advocate of the party that has retained his services. He has sworn to tell the whole truth, but, like Ananias, he withholds the greater portion of it, and if the punishment which befell that ancient prevaricator were meted out to the medical expert he would soon become a *rara avis*.

Somebody has divided expert witnesses into three classes. He says: "There is the liar, the damned liar, and the expert witness." Those who have followed the expert testimony in many of our criminal trials must have concluded that the first two classes largely preponderate.

Under our present *régime*, criminal trials in our courts (of justice [?]) are rapidly degenerating into low farce comedies, in which the criminal lawyer, his hired medical expert, and the criminal himself are the principal actors. Is it not time that something was done to restore to our jurisprudence the dignity which attached to it in times gone by when courts of justice were the terror of evil doers and the bulwarks of protection of the innocent and the oppressed, and not, as now, the arena in which criminal lawyers, with the aid of their medical experts, set justice at naught and make the bench, the bar, and the medical profession the laughing-stock of the community?

G. H. Balleray, M.D.

Paterson, N. J., February 10, 1897.

Surgical Suggestions.

Operative Treatment of Rectal Fistula.—Dr. A. B. Cooke (*Medical News*, November 21, 1896) gives the following important points which should be observed: 1. A careful physical examination of the lungs as well as of the entire rectum to be made in every case. 2. Pulmonary tuberculosis is not necessarily a contraindication. 3. Do not put down the knife until certain that every sinus has been divided. 4. Remove all diseased tissue. Large wounds are not to be feared. 5. Caution: The sphincter is to be divided only once and at right angles. 6. Special attention is to be given to the mucous opening. 7. Invasion of the perineum must be avoided, especially in females. 8. Systematic antisepsis is necessary if good results are desired. 9. Care and patience are required in the after-treatment. Dressings are not to be left to the family or nurse. 10. In the after-treatment two warnings are to be heeded: Complaints of unusual pain by the patient and increase of the discharge. Either of these may mean the formation of another abscess. 11. Hemorrhage and incontinence of fæces are the chief dangers. Both are amenable to treatment and should not deter from the operation.

Acute Gonorrhœa.—Dr. John D. Blake (*Maryland Medical Journal*, January 2d) writes as follows: "I confess I was not one of those who a few years ago thought that the millennium for gonorrhœa had come when the hot antiseptic-solution injection method was introduced, nor am I one of those who believe that nothing can be gained by such treatment. I regret very much to note the fact that in this advanced age many eminent medical men allow themselves to be so influenced by everything that appears new, that their writings upon almost any subject are so extreme and exaggerated, and the claims they make for this or that remedy or method so often overstated, that one sickens at the promptness with which he fails to obtain anything like the results claimed for a certain remedy or procedure."

Anæsthetics.—Dr. H. H. Odrich (*Canadian Medical Review*) makes the following suggestions with reference to the administration of chloroform: 1. If the patient expectorates or moistens the towel with his breath, one can change to another spot to get a more even evaporation. 2. It is well to change occasionally to a fresh, dry part, to be able to see how many drops are falling. 3. The towel covers the eyes and prevents the vapor irritating them—a point with children. 4. A small corner may be used to hold near the nostrils in face operations, out of the surgeon's way.

Alcohol in Cancer.—Dr. Hasse writes, in the *Semaine Médicale*, June 6, 1896, that he has used injections of alcohol for more than twenty years in the treatment of inoperable cancer, and four cases of this kind thus treated are now cured. He uses the same method in cancer of the breast, and believes that cure could be effected in these cases by surrounding the breast with cicatricial tissue by means of alcohol injections. It is preferable to extirpate the breast and treat recurrences by the injections. In this manner he obtained radical cure in a case declared inoperable by Volkmann.

Do Grape Seeds Cause Appendicitis?—Dr. Edward Andrews (*Journal of the American Medical Association*, December 5, 1896) says that the following conclusions are reasonable and mainly true: 1. The appendix is not a "functionless" organ. It produces every day a quantity of tenacious mucus to lubricate the cæcum, and by thus facilitating the fæcal movement prevents impaction in the head of the colon. 2. The current of this tough mucus is toward the gut; hence seeds and other foreign bodies cannot enter the appendix in opposition to the movement as long as the organ is in a healthy condition. 3. From various causes perforations may occur in the appendix. The current of mucus is then reversed and flows outward, and small bodies in the colon may thus be drawn into the appendix, or even carried through it into the abscess or the peritoneum, without being the cause of the perforation. 4. There is no scientific proof that grape seeds are any more dangerous than the hundreds of other small objects which we daily swallow with our food.

Meconium and Sepsis.—Dr. Remy (*Rev. Méd. de l'Est*, March 15, 1896) insists that the membranes should never be broken before complete dilatation without very good reasons for so doing. When the waters escape, meconium is mixed with the liquor amnii, the uterine cavity is soiled, and, if labor be prolonged and antiseptic precautions are impracticable, the fluid mixture decomposes rapidly and septic infection becomes certain. Dr. Remy distinguished the above conditions in seven labors under his observation. The mortality was forty-two per cent. Antiseptic precautions are especially needed in cases of premature rupture of the membranes.

Influence of Sea Air upon Affections of the Nose, Throat, and Ears.—Dr. Lavrand (*Arch. Internat. de Lar., Rhin. et Otol.*, vol. viii., No. 6) thinks that residence in the cold regions of the northern French and Belgian sea-coasts gives good results in the treatment of chronic affections of the ear, nose, and throat, excepting in those cases in which the ear suppurates either constantly or with intermissions, in sclerosis of the middle ear with tinnitus, and in affections of the nose and throat in individuals subject to tuberculous or arthritic laryngeal congestions.

Anastomosis Buttons or similar mechanical devices should be employed in intestinal work only when the patient is *in extremis*.—M. H. Richardson.

Acute Inflammation.—As regards the prognosis in cases of acute inflammation, questions which are constantly asked by the patient are: How long is the trouble going on? and Does it show any signs of improvement? These are difficult questions to answer; but we may take it that if an acute inflammation lasts for more than three or four days, it will almost certainly go on to suppuration; if, on the other hand, it is noticed after three or four days that the skin, instead of being tense and shiny as the result of the great distention from the exudation, becomes wrinkled, the inflammation is subsiding and will probably do so without the occurrence of suppuration.—Frederick Treves, *System of Surgery*, vol. i., p. 71.

Callous Ulcer.—A blister applied over the thickened issues around the ulcer is one of the most rapid methods by which the disappearance of the exuded materials can be brought about.—W. Watson Cheyne.

Under What Circumstances is the Surgeon to Use Chloroform in Preference to the Less Dangerous Anæsthetic, Ether?—1. In hot climates where ether is inapplicable and where free circulation of air increases the safety of the patient. 2. Chloroform may be used whenever a large number of persons is to be rapidly anæsthetized, as on battlefields. 3. Its employment is indicated in cases of Bright's disease requiring the surgeon's attention, owing to the fact that anæsthesia may be obtained with so little chloroform that the kidneys are not irritated, whereas ether,

because of the large quantity necessarily used, would irritate these organs. Quantity for quantity, ether is, of course, the less irritating of the two. 4. In cases of aneurism or great atheroma of the blood-vessels, when the shock of an operation without an anæsthetic would be a greater danger than the use of the anæsthetic, chloroform is to be employed, since the greater struggles caused by ether and the stimulating effect it has on the circulation and blood pressure might cause vascular rupture. 5. In children or adults who already have bronchitis, or who are known to bear ether badly, or, in other words, have an idiosyncrasy to that drug, chloroform may be employed. 6. Persons who struggle violently and who are robust and strong are in greater danger from the use of chloroform than the sickly and weak, probably because the struggles strain the heart and tend to dilate its walls.—Drs. Hare and Thornton, *The Journal of the American Medical Association*, 1893.

Malignant Neoplasms.—1. The mixed toxins of erysipelas and bacillus prodigiosus exercise an antagonistic and specific influence upon malignant tumors, which influence, in a certain proportion of cases, may be curative. 2. This influence is slight in most cases of carcinoma (including epithelioma); most marked in sarcoma, but varies with the different types, the spindle-celled form showing by far the greatest influence. 3. The action of the toxins is not merely local in character, but systemic. 4. The toxins should be used only in clearly inoperable cases, or after primary operations to prevent recurrence. 5. The results will vary greatly with the strength of the preparation, the most virulent cultures giving the best results.—Dr. R. Harvey Reed, *The Physician and Surgeon*, November, 1896.

Appendicitis Cæci.—Some surgeons, as Murphy, of Chicago, and other Americans, believe it is better to operate in every case in which the four cardinal symptoms of appendicitis are present, viz.: 1, A sudden attack of pain over that part; 2, nausea or vomiting; 3, elevation of temperature; and 4, local tenderness about McBurney's point. Most European surgeons adopt a more conservative course, and, except in recurring cases, wait for serious symptoms.—Dr. Atherton, *The Maritime Medical News*, p. 387, December, 1896.

The Essentials in Securing Ideal Healing.—These are: 1, Asepsis; 2, absence of avoidable trauma; 3, complete hæmostasis; 4, dryness of the wound surface; 5, accurate approximation of wound surfaces; and 6, rest during the healing process.

Treatment of Cancer by the Essence of Chelidonium.—Medicine is so powerless in cancerous tumor that we ought to welcome every new therapeutical measure presented by a man worthy of confidence and supported by proofs. Dr. Denessenko employs chelidonium internally, in doses varying from one and one-half grams to five grams daily in aqueous solution. At the same time he makes injections into the tumor, near the border of the healthy tissue, with a syringe filled with a mixture of equal parts of extract of chelidonium, of distilled water, and of glycerin. He makes this injection at different parts of the tumor. It is preferable to prepare a fresh solution daily or to add one gram of chloroform to two hundred grams of the solution. If the neoplasm is ulcerated, he paints on a solution containing from one to two parts of chelidonium to one part of glycerin. The injections provoke a sharp, cutting pain, general weakness, a chill, and fever. All these symptoms disappear on the following day. After a few days of treatment, the tumor becomes soft and seems to diminish in size. Some days later, fistulous passages form about the points where the needle of the syringe has passed, around which the tumor disappears. From sixteen to twenty-five days later the diseased parts separate from the healthy tissues, which seem to retract. The tumor diminishes in size, and sometimes entirely disappears, together with the adenitis.—*L'Abeille Médicale*, November 7, 1896.

Atrophic Rhinitis.—The *Clinical Chronicle*, May, 1896, summarizes an article on this subject as follows: 1. Atrophic rhinitis is a genuine, distinct disease of the nose. 2. It is never a sequel or later stage of true hypertrophic rhinitis. 3. It is not caused by syphilis, tuberculosis, or scrofulosis. 4. It is a disease of the female sex. 5. It is caused by a true degenerate process of the trophic fibres or root which supply the parts of the nasal membrane involved. It is, therefore, essentially and primarily a nerve disease. 6. Being primarily, then, a degenerative process of the nerve fibres or centre, it is never completely curable. It may be arrested, perhaps, and sometimes is, at some stage of the process. 7. Its treatment is symptomatic—local and constitutional. Local treatment consists in a thorough systematic cleanliness of the parts involved, personal attention to the removal of all crusts, restoration of the function of the membrane as far as possible, and prevention of the consequences of the nasal trouble on the naso-pharynx, pharynx, larynx, and trachea. Constitutional treatment consists of remedies directly in accord with the theory of nerve degeneration advanced, as well as general building up of the system, and the stamping out of any dyscrasia that may be associated with, but not the cause of the disease. 8. The disease should better be termed trophic rhinitis than atrophic rhinitis, the atrophic condition being a symptom only.

The Drainage of Wounds.—Maj. Charles Adams (*The Medical Standard*, December, 1896) considers that drainage must be employed when there is free pus in the tissues or cavities; in all infected wounds; all wounds that have been disinfected by chemical irrigation; all wounds whose surfaces have been devitalized by traumatism, operative or otherwise; wounds in very thick adipose tissue, the oil poured out in such incisions being inimical to healing; amputation wounds, in which the flaps are thin; wounds of the neck wherein extensive connective-tissue planes are opened; penetrating and perforating wounds of the brain; all closed wounds whose surfaces cannot be approximated accurately by suture or compression (cases in which under absolute asepsis we expect filling of cavities by blood clot). Drainage should be also employed in cholecystotomy (tubular drainage of the gall bladder); in operations on the common duct (tubular drainage surrounded by gauze packing); operations upon pancreatic cysts (tubular drainage after attachment of cyst to anterior abdominal wall); hydronephrosis and pyonephrosis (lumbar tubular drainage); tuberculous ascites (tubular and gauze drainage combined); all cases of abscess involving any part of the peritoneum in its wall (tubular drainage); all cases of operation upon the peritoneal cavity, when copious serous effusion is to be expected.

Injury to the Ureter.—It is necessary for the purpose of performing uretero-ureteral anastomosis: 1. That the two ends of the ureter be perfectly free and easily brought together. 2. That the bladder end be more patulous (or capable of being made so) than the kidney end. 3. That the injury to the ureter be sufficiently high in the pelvis to enable the surgeon readily to carry out the necessary manipulations. In the case of uretero-cystostomy but one point is necessary:

That the injury be not too high in the pelvis to enable the kidney end of the ureter to be approximated with the bladder.—Baldy.

Styes.—A stye may often be aborted by the vigilant application of a hot boric-acid lotion, or by an ointment of the yellow oxide of mercury. Should suppuration appear, an incision parallel to the edge of the lid should be made.—De Schweinitz.

Ingrowing Nail.—Henry Ling Taylor's plan is to lift the nail edge away from the irritated granulations by means of a hook bent from a strip of silver, about one inch long, three-sixteenths inch wide, and one-one-hundredth inch thick. The edge of the nail rests on the hooked extremity, while the shank of the hook curves over the side of the toe and is held in place by a turn of adhesive plaster. Cases even of long standing, when properly managed, yield to this treatment in a few weeks.—*American Journal of Surgery and Gynecology.*

Eucaine provokes hyperæmia at the point of application, and should be used with reserve when hemorrhage is to be dreaded. In an instance of bladder tumor, Görl (*Ther. Monats*) observed abundant hæmaturia after its use. Five minims of a ten-per-cent solution are sufficient to inject into the gum for the painless extraction of teeth. Three to five minims at the root of each tooth is better than a larger dose for a number at once.—Wolff.

Operation During Shock.—The method and manner of anæsthetizing are also important matters. Both of the commonly used general anæsthetics, ether and chloroform, I have found weakening. To reduce this effect to a minimum, it is important to employ small doses and to continue the inhalation as short a time as practicable. In order to facilitate this I have found morphine, given in a moderate dose, hypodermically, ten minutes before the anæsthesia is begun, to be a very reliable and valuable agent: it materially assists in the anæsthesia and markedly lessens the quantity of the anæsthetic required. The manner of giving the anæsthetic is also important. Forcing and smothering ought to be sedulously avoided. Whatever cone is used, it should be borne in mind that in these weak conditions a liberal admixture of air is necessary. The degree of anæsthesia should never be profound, but simply confined to the stage of loss of reflex and partial relaxation. The anæsthetic should be entirely discontinued as soon as the suturing of the stump is begun. Usually, with the use of morphine, the state of anæsthesia continues long enough for the operator comfortably to place and tie his sutures.—W. L. Estes.

Tuberculosis of the Testicle.—1. In suppurative cases with fistulæ, in which epididymitis and testicle are almost destroyed, it is best to try to prevent the spread of the disease, without operation, by deep cauterization, drainage, iodoform gauze, etc. Castration may be inevitable. 2. In non-suppurative cases in the adult, the treatment should be constitutional and expectant: recovery often follows. 3. In non-suppurative cases occurring before the twenty-fifth year, the affected part is to be removed, but the resection should be confined to the diseased tissue, *e.g.*, the epididymis alone.—Tillaux.

Appendicitis.—Dr. Sonnenburg (Congress of the German Surgical Society) divides appendicitis into seven groups: 1. The structure of the appendix is normal, but it is surrounded by solid adhesions. Clinically there are attacks of slight appendicitis with intervals during which the iliac fossa is painless. 2. The appendix is hypertrophied, indurated, and fixed by adhesions. The symptoms are the same as those of the preceding group, except that in the intervals the fossa remains full and tender. 3. The appendix is chronically inflamed and contains fæcal concretions. Clinically the same as the preceding group. 4. The appendix is ulcerated, and the concretions are surrounded by purulent matter. The cavity may be shut off and the pus may not produce violent peritonitis if it gains access to the abdominal cavity. 5. The appendix is surrounded by a purulent exudation, which may lead to secondary septic infection. 6. Perforation of the appendix leading to circumscribed perityphlitic abscesses. 7. Perforation of the appendix with the gravest complications—purulent peritonitis, multiple abscesses, pyæmia.

Operative Treatment of Inguinal Hernia.—Dr. J. Coplin Stinson (*The Canadian Practitioner*, December, 1896) describes in detail what he considers to be the preferable operation for the cure of inguinal hernia. 1. The external incision begins nearly on a level with the anterior superior spine, is carried obliquely downward parallel with and about one-half an inch above Poupart's ligament, and ends at the centre of the external ring. 2. The incision divides the structures superficial to the aponeurosis of the external oblique: the latter is well exposed and a director passed through the external ring beneath this layer, which is slit up to about one-half an inch above the internal ring: the cut edges are lifted up and freed from structures beneath, exposing internally the internal oblique and transversalis muscles, and sometimes the rectus externally, till the shelving sharp edge of Poupart's ligament is clearly seen. 3. The cord and sac are examined, and any adhesions to surrounding structures separated. Next they are separated from each other well up within the internal ring. The sac is carefully examined and opened with a sharp snip of the scissors; the opening is enlarged with the fingers, and if any adhesions exist internally these are separated. If the contents are omentum, and are matted together, thickened, or inflamed, or in any other manner changed, it should be tied off. Each vessel in the omentum is to be ligated separately, and even the smallest oozing vessel must be tied. Hold up the sac after removal of its contents, and where it merges into the general peritoneal cavity close it with a running suture of fine catgut. When released the sutured edge immediately slips back into the abdomen. The cord and its vessels are then examined, and any varicose or superfluous veins excised high up within the internal ring. Examine the canal for masses of adipose tissue, which should be removed. 4. Expose the internal ring—an opening into the transversalis fascia—by retracting the internal oblique and transversalis muscles. Any masses of adipose tissue which may crowd into the ring from the subserous tissue should be removed; take the cord and place it at the lower angle of the internal ring. Now close the internal ring with a sterilized chromicized tendon suture, commencing at the upper angle; suture from above downward, leaving only sufficient room at the lower angle for the cord and its full vessels to play through. The edges of the aponeurosis of the external oblique are retracted, and the edges of the internal oblique and transversalis (sometimes the edge of the rectus on the inner side) and the shelving edge of Poupart's ligament on the outer side are brought together with three or more interrupted chromicized tendon sutures: the cord is situated beneath the above layers of sutured structures: at the lower angle close to the pubic bone only sufficient room is left for the cord and its full vessels to play through. 5. The divided edges of the aponeurosis of the external oblique are brought together with a continuous tendon suture. 6. The skin edges are brought together with a continuous catgut suture, without drainage.

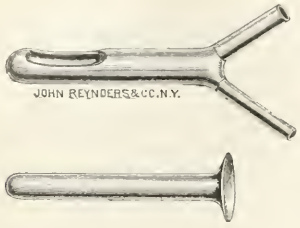
New Instruments.

A PROSTATIC COOLER AND A GLASS TUBE FOR THE APPLICATION OF ICE TO HEMORRHOIDS.

By ROBERT COLEMAN KEMP, M.D.,

SURGEON TO THE CHURCH INFIRMARY AND DISPENSARY, NEW YORK CITY.

THE prostatic cooler is a small, closed glass tube, about four inches long, rounded at its apex, and flattened just behind this on its upper surface for about



an inch. It is closed also at its outer extremity, except at two points; near the upper part a glass tube enters it, as shown in the illustration. This is for the entering current, and serves for the attachment of the tube of a fountain syringe. Near the lower part of the outer extremity is another glass tube, about half the diameter of the upper tube. This serves for attachment of a small soft-rubber tube, to carry off the outflow. The tube keeps full through the application of the well-known principle, the entering current being twice the diameter of the outflow. The tube should be allowed to fill in the vertical position, to drive out the air. It should also be allowed before insertion to become nearly of the temperature of the fluid employed. This avoids all danger of cracking after insertion. The glass tubes have the advantage of being clean and extremely cheap. They are made in several sizes: Diameter, one-fourth inch, for sensitive cases; three-eighths inch, the best for general use; one-half inch; and five-eighths inch.

I have employed all degrees of cold, even iced water. On the other hand, though the instrument is denominated a cooler, I have employed hot water at 120° F. In the larger sizes, by colored fluids, it is easy to demonstrate that there is a slight current which extends to the apex of the tube. Most of the cold or heat is obtained through conduction in the water and glass tube itself. If we pinch tightly the entering current, the outflow will immediately stop, the tube remaining full by reason of the atmospheric pressure exerted at the point of outflow. As we gradually loosen up on the tube, as soon as the pressure from above is greater than the atmospheric pressure the water begins to flow. If we attach a clip laterally to the tube of the fountain syringe, we can thus make the bag of iced water last a considerable length of time. If the clip were attached to the carry-off tube, the pressure from above might crack the tube. These tubes can also be ordered in metal, if desired.

I have employed them in acute congestion of the prostate—cold water; chronic enlargement, irritable bladder—hot water, relieving the latter; also in internal hemorrhoids. Similar tubes are made—diameter one-half or five-eighths inch—but without the depression on the upper surface, for the application of heat or cold in the vagina.

I have experimented with closed tubes of soft red rubber, furnished with a glass Y for entering and outflow currents, in the mechanical proportions named. The rubber is an extremely poor conductor. Iced water, with considerable ice and salt, furnishes only a moderate degree of cold. On the other hand, the hot water was less satisfactory in proportion, boiling water giving only very moderate heat. I employed various thicknesses of rubber, even to about the thinnest that could be introduced without a director, *i.e.*, the covering of a dilator. The white rubber seems a better conductor, and in addition, the surface of course being extremely small, I found I could get sufficient heat by attaching a small tube to a steam atomizer and conducting the steam into the tube just as water. This method is awkward, and unless carefully regulated will burn the patient, as the tube readily heats up with steam to a high degree. In the ordinary hot-water bag the surface is much larger. I have applied this same principle to it, and have found the result satisfactory. It consists practically of a soft-rubber (thin) water bag, with a small central core of wire or hard rubber as an introducer, and the same mechanical arrangement of entering and return flow. It is described in the *American Medico-Surgical Bulletin*, September 26, 1896.

The glass ice tube for hemorrhoids is practically a test tube of thick glass, four inches long, with a wide flange at its mouth to prevent it slipping into the bowel. It is to be filled about two-thirds with pulverized ice and salt, and a cork inserted. It is an extremely simple method of applying ice, and seems to aid other methods in internal hemorrhoids. The tube should become tempered to the cold before inserting. These tubes are made in several sizes—diameters one-fourth, three-eighths, one-half, and five-eighths of an inch. The three-eighths inch tube is the best size for general use. I often begin with the one-fourth inch tube, and then use the three-eighths inch.

449 PARK AVENUE.

THE CLINOSCOPE.

By GEORGE T. STEVENS, M.D.,

NEW YORK.

SEVERAL subjects of much importance in physiological optics have presented difficulties to investigators and have been viewed from radically different standpoints by distinguished authorities, because of the absence of definite and sufficiently accurate methods of examining the phenomena on which the investigations have turned. Among these controverted questions is that of the actual direction of the apparent horizontal and vertical meridians of the retina.

The doctrine of a declination of the vertical meridians, as indicated by the experiments of Volkmann and as accepted by Helmholtz, has not been received by some other investigators with unquestioned assent.

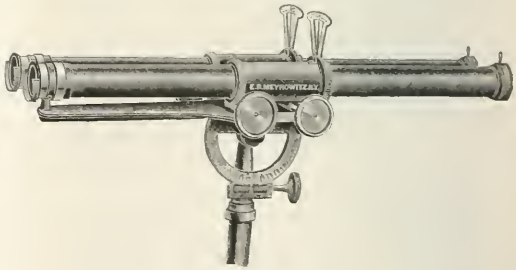


FIG. 1.

Researches of my own in this interesting field have

led to the construction of an instrument of precision, which I think will prove of value in this inquiry and in inquiries allied to it.

The instrument, which I have called the clinoscope (Fig. 1), consists of two cylindrical tubes, each about three centimetres in diameter and fifty centimetres in length. The tubes are mounted on a brass platform, which holds them firmly in the same horizontal plane, at a distance of 6.5 centimetres between the centres at the fixed points. The attachment to the

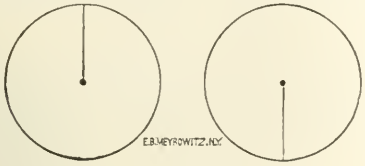

Fig. 2.

platform permits the tubes to be adjusted in parallelism, in convergence, or in divergence in the plane of the platform. The platform is attached by a movable joint to the upright standard, so that the instrument may be given any desired dip; and a scale and pointer indicate, as in the case of the clinometer, the dip with respect to the horizon.

The tubes are caused to rotate upon their longitudinal axes by means of thumb screws, as seen in the figure, and the pointer and scale above the tubes mark the rotation with accuracy.

At the proximal end of each tube is a clip, in which, if desired, the observer may insert a glass for the correction of his refraction, or any glass from the trial case.

At the distal end is another clip and provision for maintaining precise position of the diagrams to be used in the investigation. These diagrams are haploscopic figures, calculated to aid in the various experiments which may be made. These may be varied according to the wish of the investigator. Below are represented three pairs of these diagrams. Fig. 2 represents two pins, one to be seen by each eye. As the trained observer looks into the tubes, the two tubes and the two pins blend as one, and the head of the long pin now appears in the middle. An adjustment of the tubes by rotation on the long axis will show the true direction of the meridian, vertical or horizontal, according to the position of the diagrams, of each eye upon the scale above the tubes. For one who desires to test the accuracy of Helmholtz's theory of the leaning of the vertical meridian upward and outward, while the horizontal meridian remains horizontal, Helm-

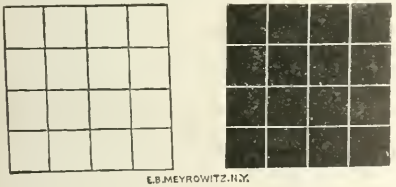

Fig. 3.

hôltz's diagram (Fig. 3), familiar to students of physiological optics, may be used.[1]

For testing the ability of the eyes to rotate upon the antero-posterior axes (torsion), a straight line running across each disc (Fig. 4) is the most useful figure. The lines may be placed vertically or horizontally. It will be found that the rotating ability is much greater when the lines are vertical.

[1] The engraver has represented these diagrams as quadrilateral. They are in fact circular, like those of Fig. 2.

The clinometer is primarily an instrument for physiological research, but as a practical instrument I have already found it of much value in determining the declination of the meridians in paralysis of the eye mus-

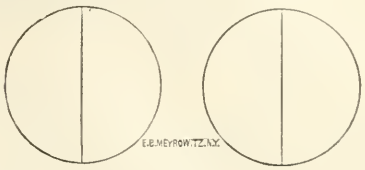

Fig. 4.

cles and in anomalous adjustments of the eyes in respect to the horizontal visual plane; and those who may be interested in determining the power of torsion or who hope to increase the torsional ability by exercise, will find the clinoscope a correct measure in the first case and an efficient aid in the second.

For the excellent mechanism of the instrument I am indebted to the skilful workmanship of Mr. E. B. Meyrowitz, of this city.

33 West Thirty-Third Street.

COMBINED WIRE SCISSORS AND EXTRACTOR.

By WILLIAM L. BRADLEY, M.D.,

NEW YORK.

This instrument, which I recently devised, was invented with a view to lessening the time usually required in the removal of sutures from the cervix uteri. It is so constructed that when once the loop of the suture is drawn down by the tenacular extremity of the scissors it can be divided and immediately removed without the necessity of laying down the ordinary wire scissors and applying a wire clamp. In some vaginæ with collapsible walls, the process of removing cervix sutures is a very tedious and long operation. It not only taxes the patience of both patient and operator, but necessitates the expenditure of much more time than the technique of such an operation should require.

The instrument itself consists of the regular wire scissors, in which one of the jaws is so projected outward as to form a tenacular extremity. Near the extremity of each blade of the instrument there is constructed a small rectangular plate, which comes in close contact with that of the opposite blade when the jaws are approximated. The opposing surfaces of these plates are corrugated, so that when once a suture comes within their grasp no escape of the same is possible.

The mechanism of the instrument explains itself.

The suture is simply retracted, divided, and extracted at one time. The instrument works equally well, whether it seizes at any part of the loop or at the knot.

The instrument is manufactured by Tiemann & Co., of this city.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 20, 1897:

	Cases.	Deaths.
Tuberculosis	248	140
Typhoid fever	6	2
Scarlet fever	174	9
Cerebro-spinal meningitis	6	6
Measles	147	8
Diphtheria	120	30
Laryngeal diphtheria (croup)	8	4
Chicken-pox	16	0

Tariff Fees in Prussia.—A new schedule of prices has gone into effect in the Fatherland for all medical services to whomsoever rendered. The poor are obliged to pay the minimum price fixed, and the rich can be made to pay the maximum; and the prices range from one mark for a single visit to five hundred marks for a Cæsarean section.

Increasing the Average.—In the seventeenth century the average duration of life was only thirteen years; in the eighteenth, twenty; in this century it is thirty-six. Look out for the twentieth!

They Do the Same Way Over There.—A good story is told of a rich manufacturer of footwear and a poor (*i.e.*, in the sense of not being rich) physician of a well-known European city. Mr. X—— had a maxillary tumor, which, according to the *Journal de Médecine de Bruxelles*, a surgeon had agreed to remove for the sum of 14,000 francs. All was in readiness, when an intimate friend urged him to defer the operation until he could consult the young man, who was fast gaining a reputation. Mr. X—— consented. An antisyphilitic course of energetic frictions and large doses of the iodides was entered upon, with such success that in a very short time the tumor had disappeared. In the mean time the young physician, thinking to patronize those who came to him, ordered at the establishment a handsome pair of shoes. On the first of the year the physician sent in his bill for 30 francs for the six office visits paid him. By return mail his bill came back, enclosed with one for 50 francs for the shoes. The question is, whether the patient would not have made the surgeon a present of the shoes if he had been cut 14,000 francs' worth.

Care of the Infant.—The first bath ought to be given with special care and as rapidly as possible, preferably without the tub. Lard is the best solvent for removing the vernix caseosa. When the tub is first used, the child should only be rinsed in the water after careful soaping and sponging on the nurse's lap, great care being taken to avoid draughts and undue exposure. A fairly strong and healthy child needs to be bathed once daily for at least two years, the late morning being the most suitable time. Cold baths and very hot ones are alike to be avoided. The temperature ought always to be determined with the bath thermometer, the proper temperature at birth being 100° F., during first month, 97° F.; from one to six months, 95° F.; six to twelve months, 90° F.; one to two years, 86° F. The best grade of castile soap is fittest for infants. Soaps containing an excess of alkali are apt to lead to erythema or eczema. A dusting-powder is seldom required if the skin is normal and properly dried after the bath. Talc is the best powder for this purpose, though lycopodium, pulverized rice, magnesia, and starch are almost as good. Subnitrate of bismuth is an excellent application for chafing. The scalp should be cleansed daily with soap and water until the child is six months old, and then less often. Fear of the bath can be overcome by placing a sheet over the tub and gradually lowering the baby and the sheet into the water.—*Archives of Pediatrics*, November, 1896.

Infected Heirlooms.—To become the possessor of old family relics, to step into the shoes of one's ancestors, to inherit the family mansion with all its old associations, its antique furniture, its ancient tapestry, is usually regarded as an enviable lot. Some cool headed, calculating, severely matter-of-fact bacteriologist has actually had the audacity to examine into the bacteriology of some old, beautiful, and otherwise priceless tapestries in an old country mansion. This bacteriologist found that the tapestries were teeming with micro-organic life, and that they were nothing less than hotbeds for the culture of tubercle bacilli. Will the mural adornments of the "tapestried chambers" throughout the country survive this terrible indictment? It may be that they will. But who after this will be able to look upon the "tapestried" presentments of, say, the lively "Adventures of Dionysius," the wonderful career of "Medea," or the patriotic manœuvre of "Mettius Curtius," without some feeling of repulsion which such a revelation could not fail to create?—*Medical Press.*

The Effect of Wearing Veils upon the Eyesight.—Dr. Casey A. Wood (*Boston Medical and Surgical Journal*, December 3, 1896) writes as follows: The fact that the wearing of veils is productive of weak eyesight, headaches, and sometimes vertigo and nausea, is within the experience of every ophthalmologist. Not only are these effects produced by the eye strain consequent upon the added efforts made by one or both eyes to see through or around an obstruction, but the irregular figuring on the veil itself is, in some instances, a source of annoyance to the wearer. As in other cases of abuse, the burden rests heaviest upon the weakest eyes, and probably the reason why one encounters so comparatively few instances of asthenopia directly due to veil wearing is that the embarrassed eyes are able to overcome the additional strain when the vision is normal, the oculo-muscular system in proper equilibrium, and the general health good.

The Anatomy of Rape.—Dr. W. Constantine Goodell (*University Medical Magazine*) gives the following brief summary: 1. That complete penetration, with the ejaculation of semen, is not necessary alone to constitute rape, but that merely partial penetration of the male organ between the lips of the vulvar orifice, with or without ejaculation, is sufficient. 2. That defloration of a very young virgin, even supposing that force was not used, should show evidences of rape, from the very disproportion in size between the penis and the vagina. 3. That the hymen is of the greatest value in determining whether coitus has taken place or not, notwithstanding the unanimous opinion of the older writers to the contrary. 4. That there is a line of demarcation, formed by the edge of the genital mucous membrane, within which, impinging of the male organ, with or without the ejaculation of semen, would as surely constitute rape as though complete penetration had occurred. 5. The great difficulty and often absolute impossibility of determining whether rape has been committed, when only partial penetration has been secured and ejaculation has not taken place. 6. The inability successfully to differentiate between marks of violence due to the penis and abrasions from attrition caused by walking, or some form of traumatism.

THE SEMI-CENTENNIAL OF THE NEW YORK ACADEMY OF MEDICINE.

ORATION DELIVERED BY

A. JACOBI, M.D.,

NEW YORK.

MR. PRESIDENT!

MR. PRESIDENT AND FELLOWS OF THE NEW YORK ACADEMY OF MEDICINE, LADIES, AND GENTLEMEN: One century has expanded this nation of three millions into its present population of seventy. Its democratic constitution attracted Europeans weary of class differences, prejudices, and sufferings. Liberty and equality, inscribed on its flag, opened opportunities to intelligence and diligence, roused legitimate rivalry, and developed inventive genius and independence of character. While inventive genius, coupled with industry, led to prosperity, independence of character found or fought its way out of political errors or actual calamities, sometimes without, other times with the guidance of clear-headed, unselfish, determined, and consistent leaders. But a young nation in its infancy has, properly speaking, no preconceived designs. It is like a product of nature, unfolding spontaneously. In evolving its organic life it rises to self-consciousness, and possibly to the development of an ideal.

It was on the same democratic basis that one-half of a century ago the New York Academy of Medicine was founded. But it differed from the national commonwealth in this, that it required no time to exhibit concerted aims or definite plans. Nor was it without an ideal from its beginning. It was well understood that our Academy was to differ materially from what is called an academy of medicine in Europe. A European academy is always a government institution, in some way or other supported by centralized national means. Its members comprise the intellectual and sometimes the social heads of the profession only. Young faces are but seldom seen among its fellows. Membership is, as a rule, obtained after a long life of successful scientific pursuits only. Their labors and efforts are not intended for practical aims or objects, but they become beneficent by the action of that logical force which ordains that there is no scientific result, no truth ever so abstruse, but will finally terminate in some tangible application. Though all this be true, the limitation and exclusiveness of membership results in a sort of aristocratic estrangement from the masses of the profession, and still more from the community at large.

The New York Academy of Medicine has a broader basis. The high and lowly, the old and young, the mature and the youthfully ambitious, though they represented the most different and various types, combined for the same purposes.

According to a circular issued years ago, in the possession of many, the Academy is not connected with any school or college. It is self-supporting, and carried on in the interest of the whole profession. There are no fees or emoluments of a private or individual nature. It is a democratic community, with equal duties and rights. It is not subsidized by the State or municipal corporation. Its aims are the elevation of the profession to a higher scientific standard for increased public usefulness. We claim that these aims concern the public as much as they do the profession. Increased scientific attainments on the part of the medical men of the country secure to the people great advantages and more effective service. Here it is that the interests of the nation and of the profession meet. Ay, I shall prove to you that the immediate interests of the whole community have for many years been uppermost in the creed and in the deeds of the Academy. Indeed there is abundance of evidence to demonstrate that the Academy deserves the general interest and sympathy exhibited to-night by so many distinguished not only in society but in all the professions, and in literature and science; ay, by the Chief Magistrate of the nation.

The history of the New York Academy of Medicine as a scientific institution is contemporaneous with that of modern medicine as created by Virchow and the German school which rapidly rose and broadened into scientific cosmopolitanism. In this wonderful evolution the Academy has freely participated. It was fully prepared for it by its ancestry. That ancestry was Anglo-Saxon medicine, which, since Sydenham, never swerved for any length of time nor suffered from philosophical theories built on clouds, or from the chaos of mysticism which reigned supreme in a part of the European continent during the first half of this century. The American medical profession, like its Anglo-Saxon ancestry, was penetrated by the spirit of intelligent scrutiny. The best of the one hundred and eighty-four founders of the Academy developed it, the plainer men shared it. The fifty years of its existence have furnished wonderful proof of the facile adaptation of Anglo-Saxon clinical empiricism to the equally solid results of modern pathology, histology, and bacteriology.

The very first paper printed in 1847 for the Academy was a historical sketch, by Pliny Earle, of the institutions for the insane in the United States of America. Much later, in 1861, Parigot read his paper on moral insanity in relation to criminal acts. The interest in that all-important subject, so replete with dangers both to the actual or alleged criminal and to human society, has never died out in the Academy, until it could sustain a few years ago the movement to transfer our insane to State care, with which the name of Louisa Lee Schuyler will forever be indelibly connected. The report of a committee upon the comparative value of milk formed from the slops of distilleries and other food, in 1848, was followed by one on solidified milk, in 1854, and another one on city milk, in 1859. William H. Van Buren's and Gurdon Buck's papers on tracheotomy in croup, and Van Buren's on hip-joint amputation, were read in 1850. Valentine Mott's (the first to operate for aneurism of the innominata) remarks on the importance of anæsthesia from chloroform date from 1848; his case of aneurism and ligature of the left subclavian artery from 1851. Not long after, C. E. Isaacs communicated his original work on the structure and physiology

of the kidney, 1856; and John C. Dalton his memorable researches on the anatomy of the placenta in 1858.

Some time previously the accessibility of the larynx and bronchial tubes was first proven in the Academy by Horace Green—that was more than forty years ago. The cholera epidemics of previous times were the subjects of papers, thoroughly enjoyable to-day, by John W. Francis. The diphtheria discussion of January, 1860, was an incentive to observation and study all over the States and beyond. Gurdon Buck invented his and our present method of treating femoral fractures, in 1861. J. Marion Sims, whose statue adorns Bryant Park, benefited mankind by his silver sutures, by improved and by new operations, and by many papers and discussions. John Watson wrote for the Academy his learned history of medical men in ancient times in 1856. On the floor of the Academy J. Toland Metcalfe, and P. Camman had facilitated diagnosis by the double stethoscope, still in use, taught his brilliant theories of the functions of the pleura and of the respiratory murmurs.

Not long after, 1863, Louis Elsberg instructed the profession in the topical medication of the larynx and neighboring organs under sight. John C. Dalton spoke on "Vivisection, What it Is, and What it Has Accomplished," in 1866; and the Academy published Robert T. Edes' prize essay, 1869, on the physiology and pathology of the sympathetic or ganglionic nervous system; also a report of William C. Roberts on the causes of death and disease in the metropolis, 1868. There were also notable discussions on cholera, on chronic metritis, on ventilation, and on sanitary police in 1866, and the paper in 1867, by A. C. Post, on the curative effects of blood letting. There were contributions by Willard Parker, Alonzo Clark, Austin Flint, and a host of others, whose names will not be forgotten, though they be not mentioned here. For it cannot be my intention to review all the Academy has accomplished during its lifetime. What I have told you refers to those whose faces and voices are known to our memories only. Indeed, while I was glancing over the sacred list of the one hundred and eighty-four founders, my eye was arrested by at least forty names of men who by original investigations and contributions have deserved well of the science and art of medicine.

As to those still living, a single allusion must suffice. One of the later great results of academic work was the memorable discussion on intubation of the larynx in croup, on June 2, 1887. It followed the discoverer's long continued labors and his paper on "Intubation versus Tracheotomy," and carried the renown and influence of American ingenuity all over the globe. Let me also mention the debates of last year on the diphtheria antitoxin, which have contributed much to the study and dissemination of the employment of that beneficent antidote.

Such are the method and line of work by which this American institution has exhibited its power, enlarged its sphere of influence, and rivalled the countries of old Europe. Such is the kind of competition as is bid a hearty welcome all over the world. That is the only kind of interference with and combination against Europe which, without collision, but with co-operation, is worthy of the great American people. There is your reciprocity without a treaty, indeed not only reciprocity of mutual giving and taking, but the proof of intellectual solidarity and fraternity of civilized mankind.

The distinctive feature, however, of the New York Academy of Medicine, as a peculiarly American institution, is not its merely scientific work. This it has in common with similar organizations in monarchical countries. Its characteristic superiority consists in this, that it is composed of citizens. The American is or ought to be, the "*zoön politikon*," the political creature of Aristotle, a co-operative cell in the organism of society. From that point of view let me glance over the fields on which you will find the members of this association in full activity; let me indicate what they are doing for you individually as practitioners: for you as a community as sanitarians, to the utter neglect of self-interest; let me also show the relation of the Academy to its own members and to other scientific bodies. Finally let me consider what it and you combined may be capable of achieving for the future of medicine and of mankind.

As practitioners, the members of the profession, academicians and others, have amply satisfied the reasonable expectations of the sick in the community. In former times almost every man, the most illustrious surgeon of the day not excepted, was a general practitioner. Specialists were not so numerous as they are to-day; indeed, there existed but few. These were men of ripe general experience, who would confine their work to a special organ or line of practice. When medical science broadened out and its progress depended on thoroughly specialistic study and research, the big old tree divided up into branches and branchlets; and in the practice of medicine the number of specialists, both mature and immature, justifiable or otherwise, increased almost incredibly. Time will be demanded to correct the mistakes and incongruities of overgrowth. Meanwhile, I am glad to be able to assure you that general practitioners still exist, and also that many specialists, known or unknown as the case may be, have not ceased to be doctors. You know them well and intimately. Your doctor is summoned night or day, by your servant, or your telegram, or telephone. You order, there he is. He is expected to aid you with therapeutical and other means—*therapos* means servant; and to cure—the very word means care. If ever there is a class of persons who deserve to be decorated with the device "*Ich dien*," "I serve," it is your doctor. He must not know, he does not know, the difference between night and day. With doleful jealousy he might hear of the efforts of philosophers, philanthropists, statesmen, and even of politicians, in favor of an eight-hour or ten-hour day. He is expected and willing to work indefinitely to lighten somebody's burden, like sun, or moon, or stars, that know of no rest. If anybody, your doctor is not the lily in the field that does not spin.

The same doctor goes a few streets to a hospital or to a dispensary. There he serves the poor, or the alleged poor. One of the hundreds of necessary and unnecessary institutions of the kind with which different grades of exigency, or philanthropy, or officiousness, or greed, or the wants of a teaching institution, have supplied the city claims his service. He meets the poor and also those who don the clothing of their servants to appear poor, sometimes those who leave their carriage and footman around the corner. He must not complain. He has heard of the woman in the Gospel who, before she applied to the Master Healer, is said to have "suffered many things from the physicians;" and concludes that the time has now come when the physician is to suffer from the many. Thus he aids, though ever so unwillingly, in robbing himself and his professional brethren, and in demoralizing and pauperizing a goodly part of the community. That is another unwelcome outgrowth of modern science and philanthropy, to correct which time and thought, and the co-operation of the profession and the public are urgently demanded.

Thus he works on and on. It is but a few weeks ago that an old practitioner told me of his life. It was all work and never so much as a vacation. Exhausted he was at night, tired in the morning. He

lived on the stimulants of duty performed and on the intellectual and moral interest he took in his work, complaining only that he could not do it to his own satisfaction. Perhaps some of you remember having gazed at a statue in Munich. It represents a youth climbing upward, passing disdainfully the golden calf to attain what he evidently believes to be a crown of laurel in the hands of the goddess. What he finally snatches is a crown of thorns. Still he climbs, maybe to reach the stars, to which Ralph Waldo Emerson bids us hitch our wagons. In spite of failures, I say to my young friends, hitch your wagon to the stars. Not everybody falls like Icarus, and the horizon enlarges from the heights. This your horizon, let it be vast; unless it be so, both the morals and the science and art of medicine will suffer. It is from that point of view also that I exhort my friends, either pure scientists or practitioners, never to forget that there is no antagonism between the two classes. The time is past, and partly through the efforts of your Academy, when the pure scientist looked upon practice as inferior, and the practitioner on pure science as beyond the pale and unpractical. Helmholtz, than whom this century has produced no more intense worker in pure science, proclaimed that mere knowledge is not the aim of man; that you may dignify it in two ways only, either by applying or by enlarging it. Knowledge without its application in the service of mankind, is like a library without readers, a museum without visitors, a symphony without hearers. Apply what you know and daily learn in the community's service. Do not forget that there is no power more worth possessing and inestimable than life and health. That truth is certainly in the minds of the American public, misguided though it be when it feels like paying two hundred million dollars, annually, for proprietary drugs. Nor should you be discouraged by what Pliny said and others credulously accept: "Say you are a physician, and you will be believed. Detract from your neighbor and you will be considered superior." Mind what you may have read over the gate of a Swiss hospital, "*Res sacra miser.*" So your community, when in danger of health or life, is "*res sacra*" to you.

What has the Academy done for its members? As a previous practice of three years in the city is required of a candidate, and the scrutiny of the committee on admission is always painstaking and fearless, the average standing and proficiency of the fellows is high and their moral tone elevated. The committee on ethics of former decades has, therefore, been abolished together with the abrogation of the official code. No authoritative body of rules is required or recognized in place of the unwritten law of gentlemen. Alleged cases of transgression are relegated to the decision of the council, but none was required for years. In the Academy of Medicine there are no professional politics. It is considered neutral ground, and the differences of schools, cliques, and combinations are supposed to be left behind when a fellow passes the entrance gate. Still, we are not all angels. That secret will come out some day, and may as well be whispered in public. That is why questions beyond the domain of the Academy are, however, forced in sometimes. That is to be deplored. Battlefields there are as many in New York City as in the Virginia Wilderness, or about Lake George or ancient Rome; but Rome had its temples of Vesta and Peace. Let the profession of New York remember and revere the Academy as the one temple of safety, impartiality, and neutrality.

To none has the Academy been of more service than to the younger members. To become fellows after a fair examination of their claims to admission is in itself an honor and improves their standing. Besides, all of the eleven sections have been in working order these twelve years. That means that eleven times as many fellows found a direct encouragement for work, both in private and in public. In the section meetings, the future officers of the Academy and teachers of the profession find a new incentive to labor and research, and are always certain of an appreciative audience.

Our relations to the public at large and to the city and State have frequently been the subject of discussion. You may have been told that we demand special class legislation. If that were true, we, democratic American citizens, should be on the level of German students before they were deprived of their clannish jurisdiction, or of the Prussian military officer, whose moral is based on his sword and sense of justice on the prerogatives of his degenerate nobility. In a few words, the public may learn the attempts on the part of the profession to secure a so-called special legislation. These twenty years we have been fighting in Albany for a preliminary education of matriculants, also for State examinations as a condition upon which alone the license to practise should be awarded. We, the Academy in conjunction with the rest of the profession, have worked to increase the duration and the number of college courses. The profession, particularly as it is represented in the Medical Society of the State of New York, has secured laws against quackery, and the Medical Society of the County of New York has undertaken to extinguish it in this city. This committee sacrifices its time, and the society its own money, to combat frauds, quacks, and diploma mills. That does not look like class egotism. You should admit it is something entirely different unless you wish a low grade of knowledge in your medical advisers.

Your Academy and your profession were ever of the opinion that there must be no free trade in human flesh. Many of your old doctors were abolitionists when this nation was still disgraced by slavery. All of the old and young members who are imbued with respect for human life and health, and with the sense of their own responsibility, have combined to do your fighting, the community's fighting, against the dangers of quackery. It is not the existence of the profession, it is the safety of you, the public, that is enhanced by your special legislation. Two things I have been told; sometimes one was that, no matter how low the standard of medical men was in some parts of the country, they were always superior to their community; the other word was, doctors were generally better than the public deserved or deserves. You can prove that such is not the case by co-operating with your doctors. We beg of you, we insist upon it, that you and your delegates, the legislators in Albany, may continue to protect you and yours from the inroads of charlatanry and ignorance. Do not forget, however, I speak here of the battle against positive ignorance, assumption, and downright illegal quackery.

The Academy does neither recognize nor fear, as in times long gone by, isms and sects, and for that very reason does not propose to war against them or even to denounce them. In its whole history of the last quarter of a century and perhaps longer, I fail to read of a case of persecution of a man or of a body of men directed against their scientific principles or prejudices. Moreover, to discuss honest scientific errors, alleged or real, in an inimical spirit is to endow them with new life. If there was animosity it has been dying fast. Not that I mean to say that the medical world was always just. Semmelweiss, who was driven by his alleged peers into an insane asylum because he preached and practised upon the knowledge of the contagion of puerperal fever, about the same time that our own Oliver Wendell Holmes wrote his wonderful

essay on the same subject, or our own Atlee, who was vilified and harassed because of his leading in an operation that at present is of daily occurrence, are evidences of shortsightedness and impressibility. Still, after having observed and co-operated with the profession in this city these forty-three and with the Academy of Medicine these forty years, I know, though errors may have crept in, that none but the purest and most altruistic motives have governed the actions of the profession. Least of all is Herbert Spencer correct when he says that "the incorporation of authorized practitioners has developed a trades-union spirit which leads to jealousy of the unincorporated practitioners, that is, the irregulars; and, like the religious priesthood, the priesthood of medicine persecutes heretics and those who are without diplomas." I trust the great philosopher's sympathy with heretics and those who are without diplomas will never revenge itself upon him and his health.

Great questions of the day have always inspired the medical profession. Both old Socrates and modern Kant expected the light pre-eminently from medicine. It is true that in the politics of our country we have but few medical combatants, compared with the good done by medical statesmen in Europe; but that of Benjamin Rush outweighs many names not belonging to his and our profession; and until the latest time physicians have participated in your reform movements. The Committee of Seventy of 1872 had among its most active members one of the most prominent men the New York Academy of Medicine ever counted among its own, Ernst Krackowizer. In public concerns the Academy was always interested. It took the initiative in many movements, the realization of which had long to wait. Medical school inspection, inaugurated just now, was urged by the profession in open meetings twenty-five years ago, and again by members of the Academy half a dozen years ago. The Willard Parker Hospital was planned and its organization pushed by a member of the Academy. Again it was a fellow of the Academy who renewed, if not instigated, the agitation for the new factory laws in behalf of women and children in 1882. Clean streets, or rather muddy and unhealthy streets, also the tenement-house question, also school houses, and the reception hospital were the subjects of many debates. It was a committee appointed, at the request of the board of health, which originally started in the Academy, and which, under the leadership of C. R. Agnew, whose mind and heart have immortalized him in the memory of those who were so fortunate as to live and work with him, reformed the quarantine of the port of New York, and elaborated the plans and estimates according to which the legislature finally restored Hoffman and Swinburne islands to their present condition. Another committee of the Academy looked after the Croton water and the watershed.

It was through a committee of the Academy that medical inspection of the eyes of all the inmates was introduced in public institutions. If that practice were continued conscientiously, and attention to the eyes of the newly born suffering from the same contagious ophthalmia were made compulsory, there would be many vacancies in our future blind asylums.

The Academy's efforts joining those of other medical bodies of the land in favor of the establishment of a national board of health, were, however, not successful. They will prove so in future. For just as certainly as this nation means to continue "now and forever, one and inseparable," its most sacred boons, viz., health and life, interdependent as they are over the vast area of the country, should be secured by uniform legislation. It was the Academy of Medicine, again, which was called upon to protect the port and the city against the invasion of cholera. That was four years ago—a long time, perhaps, for republican memories: but it is not forgotten that the committee men, though among the busiest of the city, were always at their post: that their efforts were successful and at that time appreciated; that they aided in keeping cholera out, and, at the same time, protected the commercial interests of the country. We trust the chamber of commerce has not forgotten its own estimation, as then expressed, of the Academy's services. Nor have the poor of this city, and of others that imitated its example, a reason to forget the Academy. The agitation for the establishment of free public baths was begun by one of its fellows in 1890, and has resulted in the erection of four such institutions. Two hundred and fifty thousand people availed themselves of the opportunities thus offered in a single year.

The responsibility toward both the public and the profession was always deeply felt by the Academy. Its library is free to the whole profession, fellows or not, and to the public at large. Beside medical works, it has many of interest to the legal profession. By both it will be readily admitted that there are more useful and more congenial relations between them than when they meet in a court of justice, where the medical man, clad with the mantle of partisan expertship or expert partisanship, does not shine to advantage, and is apt to contribute less to the honor and dignity of his profession than to the miscarriage of justice.

The Academy's hospitality is constantly exhibited in the cases of the numerous national medical societies which convene gratis under our roof. The Society for the Relief of Widows and Orphans of Medical Men, the Saturday and Sunday Hospital Association, the Ladies' Protective Health Association, are made welcome on the same conditions.

The Academy is recognized as their head centre by other medical societies which cluster around it. It is in its section rooms or in Hosack Hall where they hold their regular meetings; one at least gave up its independent organization to become a section of the Academy. It cannot be avoided, however, that the generosity of the Academy is occasionally abused. Now and then we hear of desirable men who refuse to join and pay the annual contribution, on the plea that without personal membership they enjoy the privileges of those who pay their dues, that is, access to the building, the meetings, the papers, and the free library and reading-room. Such occurrences do not prove much, while exhibiting the broadmindedness of the Academy, except the occasional presence in the medical ranks of selfish men. Fate made a mistake when it admitted them to American citizenship and to a liberal vocation. Membership in a profession is by itself not sufficient to ennoble a man; it is the noble man who adorns and exalts his profession.

Nor do the academicians confine their labor to their own institution or to the city. There is no national association in which they are not interested and co-operating. It was a fellow of the Academy who established a section for diseases of children in the American Medical Association. Its members are largely represented in the Association of American Physicians, and in the American surgical, pædiatric, climatological, gynæcological, and other societies. In the transatlantic congresses, the British Medical Association, and the international medical congresses, their names are frequently met with.

What I could say, fragmentary though it be, should have convinced you that the best individual and collective efforts of the profession as represented in the Academy, are being spent in the service of the community. In the same degree that the intellectual and scientific development of medicine and of the profession has been progressing, that service became more

valuable. Now, on all your lips I am reading the question: What can the community do for the science and art and the profession of medicine, and particularly for that of the city?

The monarchies of Europe, particularly continental Europe, have had medical schools these five hundred years; in this century their number increased. The facilities for teaching and learning were enlarged. In the last twenty-five years laboratories and clinics and libraries grew steadily with growing demands. The professors are salaried, their future is secured by pensions, their incidental expenses are paid, their lives are allowed to be dedicated exclusively to scientific research: for they and their children will not go hungry. All this is done without individual exertion or contributions. No matter whether wars crippled the means of the people, or whether militarism sucked the marrow of the land, or the sterile soil did not even feed the mostly agricultural population, the universities were provided for more or less generously by the government, at public expense.

With us the community is its own providence. The democratic citizens are their own sovereigns, and their means permit them to give way to their generosity. Schools, churches, nurseries, hospitals, libraries, have been its main beneficiaries. Medicine, however, has not yet received its full share. Still the benefactor of Johns Hopkins University and Hospital, the New York family that erected and endowed college buildings, laboratories, and hospitals for a medical school, the donors of the Carnegie and the Loomis laboratories, the founder of the Pepper Laboratory in Philadelphia, and of the Bender Laboratory of Hygiene in Albany, have accomplished exactly and often most generously, what is carried out by the sacrifices and exertions of whole monarchies. Again, only a week ago, we learned of the offer of a million dollars, made by a fellow-citizen, to whom our Academy also is under obligations for powerful aid, for purposes both of relief and instruction. You call that "royal"? No, ladies and gentlemen, that is not royal: it is the spirit of republican citizenship, dreamt by a Plato, realized by an American. Nor am I disposed to forget what we, the New York Academy of Medicine, owe to the New York public. It is with its spontaneous and valuable aid that we were enabled to erect the spacious and commodious building in which we hope to meet you again to-night. Though I am forbidden to mention the names of the living, I cannot abstain from recalling the ample bequest of the late Celine B. Hosack. It is to that liberality of the community that we have again appealed lately in our efforts to raise our library fund to one hundred thousand dollars. The response elicited thus far appears to justify our hope of attaining our ends in the nearest future: it certainly proves that a generous public appreciates the additional factors of learning and erudition in its skilled medical advisers.

Nor does the Academy appeal to you in its own behalf only. Every advance in the standard of medical education is a new ally to the Academy. The medical schools need endowments, like ourselves. Medical teachers are not rich: they should not be expected or made to look for a livelihood to the fees obtained from the students: that is a fact now acknowledged, and an ideal realized in the medical department of Columbia University. Laboratories of hygiene, chemistry, physics, botany, biology, should not be supported by the contributions of medical men only, or perhaps not at all. What monarchy is in the old world, that is democracy in the new, namely, the evidence and representation of the condition of its political and moral civilization. Hospitals you have built in large numbers, and in some instances more than required, and still some more are demanded. No scholar is imaginable without a library, no anatomist without a dissecting-room and a museum, no chemist or physicist or physiologist without experimentation, no medical graduate who is to practice on you and yours without instruction in a clinical hospital intimately connected with the medical school, and situated on or near its grounds. Imagine, mothers, that every year hundreds of men and women begin the practice of medicine without ever having seen a baby sick in bed.

There is many another way in which the community may render itself useful to the medical profession. See to it that no personal interest, vanity, or misapprehension interfere with the progress of medicine. It is through our own efforts that we overcame the lack of knowledge on the part of legislators, and the opposition of medical schools, when we enforced a certain amount of preliminary education and the establishment of state examinations. See that these your gains, for they are yours, be not taken away from you; they were conquered in your behalf. See that scientific study and progress are not shorn of their prerogatives, that is, experimentation, and that your legislators are not influenced except by facts. When, for instance, agitators speak to you of the cruelties of vivisection, remember that they select that hard word in order to conceal what it means, that is, animal experimentation, which is already secured and protected against barbarousness and cruelty by a well-adjusted and satisfactory law, that was passed by former legislatures and ought to be left intact. Tell them also that you know that the action of many therapeutical remedies useful to them and their children could be studied by animal experimentation only: that one of the most formidable calamities of former times, the terror of every woman who was to become a mother, childbed fever, has been reduced to the very lowest figure wherever the teachings of animal experimentation have been heeded; that hydrophobia, always fatal, has been made accessible to treatment with at least fair results; that tuberculosis may be and is in part confined within certain limits; that the prevention of cholera, even that of the plague, is no longer a dream; that the mortality of diphtheria is reduced to nearly one-half of what it was; that quite certainly the future therapeutics of scarlet fever, measles, typhoid fever, and other scourges of mankind will be based on antitoxins; that the success of surgical operations under the influence of antisepsis and asepsis is simply marvellous; and that all these blessings are the direct result of animal experimentation. Tell them also that the horse or sheep that furnishes the antitoxin which is to save American children does not even suffer, and if it comes to the worst, if rabbits and guinea-pigs have to be sacrificed by humane men armed with skill and anæsthesia, that the future ought to belong as much to mankind, ay, more to mankind, than to rabbits and guinea-pigs, or to those animals that you hunt over fences and brooks, and with the permission of the law shoot to death amidst the excited laughter of sport, but pretend to shed tears over when science tries to fathom new wonders, to establish more firmly the foundations of health and life for old and young, and to discover new means of salvation for this republic and mankind.

In what I state I identify the demands of the profession at large and of medical science with those of the New York Academy of Medicine. Ours is "*Una fides, altare commune*," one faith and a common altar. That shibboleth you will find is the sole inscription on our home in Forty-third Street. What you will do for one you will be doing for all. Whatever you do, you will contribute to the medicine of the present and of the future, and to the great work in store for it. We know that it is levity only that makes empty hypotheses, sometimes, unfortunately, even laws; that

much labor, however, and hard work are required to obtain great results. In all humility, but with earnestness, medical men tender you their labor in practice, in hospitals, on the teachers' platform, in the laboratories. What they expect and look forward to is appreciation not of the individual, but of the aggregate work, and co-operation on the part of the public, for the immediate results of our work are at the same time humane and practical. The reduction in your death rate of one in a thousand means, beyond the saving of one life, a lowering of more than thirty in the total number of cases of sickness, and therewith prevention of much anxiety, wretchedness, and financial loss or ruin in as many families. Results like these are liable to be accepted as natural; they are claimed, as it were, as the normal appendages of modern civilization. It should not be forgotten, however, that they are obtained only by the work of medical men who labor for the good they can do, often as hermits, unknown and unappreciated, always bent upon the diminution of the number of problems which hitherto were deemed hopeless. The medical searcher is like the astronomer who differentiates in nebulous distances stars big and small, luminous and dark, fixed and migrating. More than any other man, he spies for the relation and connection of things and phenomena, and becomes the true philosopher and physician, who was called godlike, by a great poet three thousand years ago.

Much of what I touched upon has been, or is being accomplished. The rapidly increasing facilities of investigation have changed the methods and aspects of modern medicine to such an extent as to make me anxious to know what the orator of the next semi-centennial celebration will have to say to you. Part of it I know, and you will know it too when I beg you to consider with me during the last minute of my address the possibilities and the certainties of medicine. Its methods of investigation will never be changed, for they have become those of natural science, and these, because they are based on observation and experimentation, are unalterable. Indeed, medicine is a part of the natural sciences; the human organism, well and sick, physical and spiritual, is the subject of its scrutiny. Man's nature, both normal and abnormal, belongs to the domain of medical inquiry. Psychology has for some time past become a branch of physiology. The sound mind, its aberrations and freaks, the soul with its holiness or turpitude, no matter whether considered by the believing philosopher or the searching materialist, are topics of biological study. The explanation and relations of most intimate physical and psychical processes are sought for, will always be sought for, by the sanitarian, the teacher, the clergyman, the judge, the statesman. It is in medicine that they will find them. The time will soon come when the culture of a nation will be estimated according to the mutual relations of medicine and the people.

Is this an ideal? It is, but no Utopia. Indeed, much of what was an ideal twenty-five years ago has been achieved. It is probably true, however, that no ideal will ever meet with its entire consummation, and ideals will be modified or expanded. Nor do I believe that even the star guiding the three sages of the East shone always with equal splendor. Thus it is possible that what I earnestly hope for in the next half century will not be completely fulfilled; but woe to the man, to the profession, to the nation, without an ideal as a guiding star. To medicine in its legitimate and just meaning that star is the improvement of man both individually and collectively. It demands and promises the combination of scientific research into the wants of mankind, with the application of preventives and remedies for its physical, intellectual, and moral dangers and defects. To keep and fortify medicine on that platform is the ideal of our calling. By working for it, medicine and medical men may create that power which alone protects individuals against hebetude or despair and nations against wreck and perdition. That power is benevolence, beneficence, and mutual assistance.

A SUCCESSFUL CASE OF EXTERNAL ŒSOPHAGOTOMY FOR TOOTH PLATE TWENTY-TWO MONTHS IMPACTED IN THE ŒSOPHAGUS, WITH SUMMARY OF ONE HUNDRED AND SIXTY-SEVEN OPERATIONS RECORDED UP TO JANUARY, 1897.[1]

By WILLIAM T. BULL, M.D.,
AND
JOHN B. WALKER, M.D.

C. L——, a maid, single, forty years old, native of Scotland, in previous good health, noticed after a slight fainting attack that an upper plate carrying two false teeth had disappeared. This was in November, 1894. The plate (Fig. 1) was of platinum, one and one-fourth inches long, three-fourths of an inch broad, irregularly indented in front, and provided with two half-circles of small wire for hooking on to the sound teeth. There was trifling pain, but next day she could swallow nothing. Dr. C. F. Barker, of Newport, R. I., found it impossible to pass a bristle probang farther than six inches. The following day liquids were swallowed, and slight swelling and tenderness were detected just above the sternal notch. The facility of swallowing increased, and she could take solid food at the end of five or six weeks. The local swelling disappeared after a few days. She had no marked difficulty and no disturbance of her general health till toward April, 1896, eighteen months from the time the plate was swallowed. Then dysphagia was noticed, with loss of flesh and strength, and feebleness and hoarseness of the voice. In four months, March to July, 1896, her weight decreased from one hundred and twenty to ninety pounds, and she took only liquid food. About the middle of July I saw the patient. She was thin, anæmic, weak; able to go about, but not to work. Pulse, 80; temperature, 98.5° F. Palpation revealed nothing, and no sort of œsophageal bougie could be passed beyond a point about seven inches from the teeth. No laryngoscopic examination was made. Rectal feeding was added to the nourishment by mouth for five days previous to operation. External œsophagotomy was done, July 27, 1896 (twenty-two months after the accident), with the help of Dr. Barker and the staff of the Newport Hospital. The œsophagus was exposed readily on the left side through tissues that showed no trace of inflammation, but the body could not be felt by the finger. The œsophagus was opened just above the sternum upon a bougie, and the edges of the incision were held apart by loops of silk. The wall was healthy

Fig. 1.—Tooth Plate (1¼ inches by ¾ inch) in œsophagus twenty-two months, removed by œsophagotomy. Recovery.

[1] Read at a meeting of the Practitioners' Society, New York, January 8, 1897.

here. An inch lower, behind the first part of the sternum, all exploring instruments were at first arrested, apparently by soft tissues. Eventually a whalebone passed through to the stomach along the anterior wall, and a probe beside it entered a pouch in the posterior wall and grated against the plate. The œsophageal wound was enlarged downward till its entire length was about one and one-half inches, and the plate grasped with a curved artery clamp; but it could not be easily extracted until the mucous membrane in front of it had been cut with scissors. These manipulations were somewhat prolonged and difficult from the interposition of the sternum. It was evident that the plate had sunk into the posterior wall and been lodged, with its long diameter vertical, in a sort of pouch of the mucous membrane, which had ulcerated at one point, leaving only the upper and lower end of the plate exposed in the lumen (Fig. 2). The wound was lightly stuffed with iodoform gauze about a large soft-rubber catheter, which reached four inches below the site of the foreign body and was brought through the dressing of sterilized gauze. The operation lasted two hours.

No vomiting followed. The temperature was 101 F., with pulse 110 for a few hours next day; then ranged from 98.5° to 99° F., with pulse of 80. For twenty-four hours only rectal feeding was resorted to; then three or four times in twenty-four hours fluids, beginning with four ounces of boiled water, were introduced though the catheter without any stomach irritation. The mouth was frequently irrigated, but nothing swallowed. Occasional cough and expectoration of mucus were quieted with small doses of morphine hypodermically. The iodoform packing about the catheter was changed three times in the first ten days, when the catheter was withdrawn and replaced by a clean one. On the thirteenth day the wound was much contracted and granulating well, and the catheter was withdrawn, leaving only a light wick of gauze down to the œsophagus. Up to this time there had been no escape of œsophageal or stomach secretions into the wound. In forty-eight hours after removing the catheter nourishment was given through the stomach tube, passed twice a day; then swallowing was permitted and rectal feeding discontinued. The œsophageal wound had apparently closed, for none of the swallowed fluids escaped. The sinus was healed entirely at the end of seven weeks, the patient having been out of bed at the end of a week. From the end of the fourth week a No. 19 (English) œsophageal bougie was passed, and this or a No. 20 introduced on alternate days during the next month. There was a rapid gain in flesh. The voice remained rather feeble and hoarse, and a laryngoscopic examination made by Dr. Powell showed the left vocal cord to be motionless. For this the faradic current was given for several weeks, with gradual restoration of the voice to its natural strength and clearness, according to the patient's statement and that of her friends; but no subsequent examination of the throat was made. Four months after the operation her condition was perfectly satisfactory.

The length of time (twenty-two months) intervening between the swallowing of this plate, and its removal without accident, make this case worthy of special note.

In the one hundred and sixty-seven cases reported up to 1897, which Dr. J. B. Walker has compiled, the only longer periods are four—viz., one of twelve years, one of three years and three months, one of two years and three months, and one of five years and nine months' duration. In fact, forty-six cases have been operated on within the first three days, seventy-four within one week, and ninety-six cases within four weeks.

The point of arrest was fortunate. It was just above the dangerous proximity of the tracheal bifurcation and the aorta, and its position made it possible to remove it without damage to the œsophageal wall. Had it been a trifle lower down, its extraction through the neck would have been impossible, for the fold of mucous membrane overlapping could not have been appreciated and divided; and the same disposition of the mucous membrane (see Figs. 1 and 2) would have made it difficult to dislodge by any efforts from the cardiac end by a gastrotomy.

Immediately after lodgement it could, considering its size and situation, probably have been removed through the mouth by the coin catcher, and certainly by a simple œsophagotomy; but it is natural, in view of the facts that the instruments were not at hand and that the dysphagia soon disappeared, that the attempt was not made. The plate, though attached to the wall, evidently offered but little obstruction to food until the mucous membrane became so folded about it as to constitute a stricture of the œsophagus. In fact, in approaching the case I did not feel at all sure whether I had to deal with the plate alone constituting the obstruction, or a stricture resulting from injury done by it, or the plate plus a stricture. The woman had not been continuously under Dr. Barker's observation, and her history was vague, and the instruments introduced gave no evidence of being arrested by a solid body. In the future an invaluable aid to diagnosis will be afforded by a resort to skiagraphy, as was done first by Dr. J. William White, whose case is recorded in *Annals of Surgery*, August, 1896, p. 238. In that case a jackstone, lodged at the level of the second and third dorsal vertebræ, was successfully removed by means of gastrotomy. As White has pointed out, the skiagraph will not only indicate the existence of the foreign body, but point out its exact situation more clearly than one can estimate it by bougies, and thereby enable us to select the proper method of treatment.

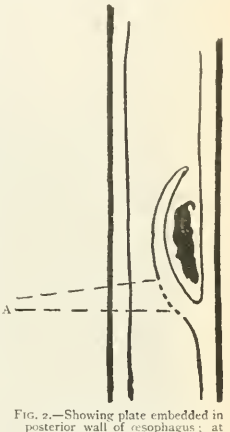

FIG. 2.—Showing plate embedded in posterior wall of œsophagus; at A, the fold of mucous membrane having ulcerated.

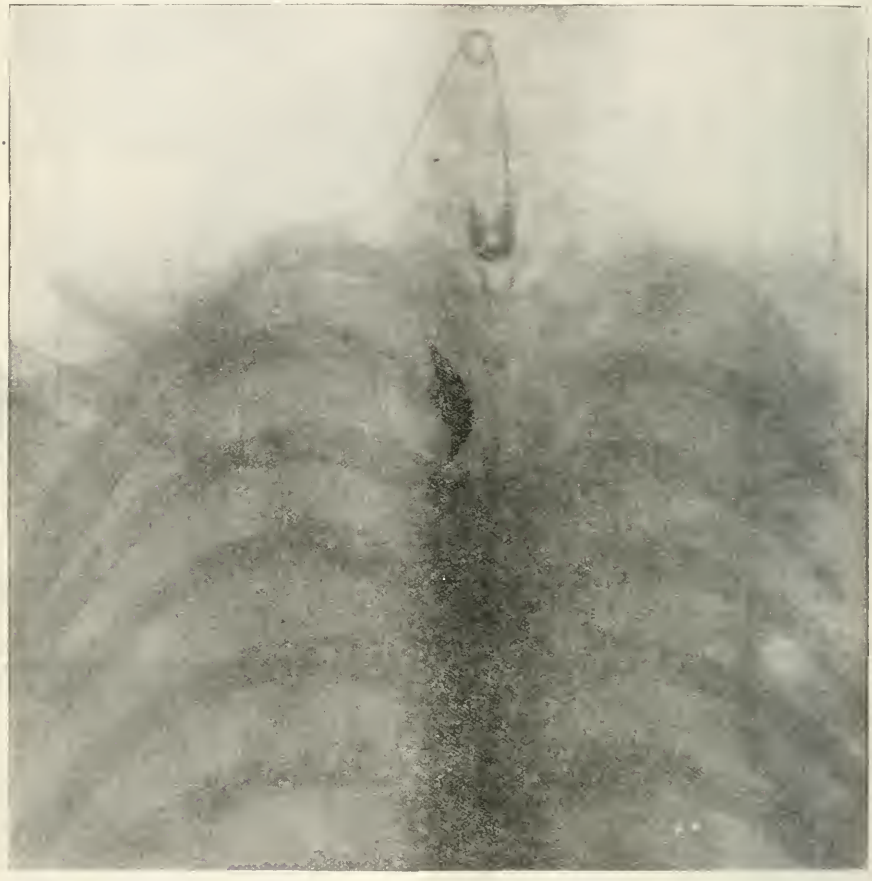
Being curious to subject this plate to the *x*-ray test, I placed it in the œsophagus of a cadaver, so as to lie wholly behind the upper part of the sternum, and got, with the aid of Messrs. O'Connor and Hawks, the accompanying skiagraph (Fig. 3). The plate was at the back. The sternum is not apparent, but the situation can be inferred from the vertebra, ribs, and scapula, which are fairly distinct. In the same œsophagus I placed a large safety pin just below the cricoid cartilage and a peach stone at the cardiac end. The pin is very distinct, but the stone escaped detection. A stylographic pen in the stomach was clearly delineated.

It is worthy of note, though not relevant here, that a sponge or a gauze compress left in the abdomen, three gall stones placed against the neck of the gall bladder, three fragments of phosphatic calculus as large as an olive, put in front of the kidney, gave no trace of their presence: but two fragments of a broken needle in the abdominal wall, a pair of forceps in the pelvis, and a shot in the appendix were recognized on the negative and depicted in the skiagraph. A uric-acid calculus in the bladder (about one and one-half inches long by one inch wide) was seen only after the subject was laid on the stomach. With the fluoroscope only the

safety pin and the forceps in the pelvis were made clear.

Egloff enumerates twenty-five different articles that have been arrested in the œsophagus. Of these, sixty-two per cent. are represented by dental plates and bones in equal proportion. Of the remainder, at least fourteen are of such materials as would likely be recognized by skiagraphy. Hence the importance of this addition to our surgical resources cannot be overestimated.

The œsophageal wound in this case healed in fifteen days, after the catheter had been worn thirteen days. It would have been unwise to atttempt suture of the wall of the œsophagus, on account of the late moment of the operation and the condition of the parts within. Not every case, however, will tolerate so quietly the presence of a tube, etc., or be so free from regurgitation of mucus into the wound. In the weak condition of these patients rectal feeding is indispensable, and it may be relied upon exclusively for several days when sutures are applied to the wall of the œsophagus. This, which is the ideal procedure, should be attempted only when the case is a recent one and when extraction has been accomplished with no damage to the œsophagus. Even then the wound outside should be protected by being kept open with gauze, though absolute primary union of both wounds has been accomplished in one instance by Post.[1] This is attended with some risk, as Richardson[2] points out. The stomach tube must be employed after rectal feeding for a day or two, according to the condition of the patient, and it may break down the union in the œsophageal wall and permit infection of the deeper parts of the wound—a condition which, at the root of the neck, is attended with much risk. With the œsophageal wound carrying the stomach tube or catheter there is some risk from hemorrhage. One case ended fatally from erosion of the internal jugular vein; but in a wound properly protected by gauze about the tube and kept aseptic this accident is not likely to happen. Dr. Walker notes thirty-eight cases in which after the operation enemata were employed for forty-eight hours and followed by feeding through the tube, all of which terminated in recovery; while in sixty-two cases where the stomach tube was left about fifty per cent. died. The total mortality of one hundred and sixty-two cases up to 1897 is 24.07 per cent.



For further statistical information, I refer to the following facts gleaned by Dr. Walker:

The first series of important statistics upon this subject were completed by Fischer in 1889.[3] It consisted of 120 cases.

In 1894 Egloff[4] brought this forward with a col-

[1] Boston Med. and Surg. Journal, December, 1893.

[2] Deutsche Zeitschrift fur Chirurgie, 29, p. 97.
[3] Beiträge zur klinischen Chirurgie, 12, 143.

lection of 15 cases. The writer has collected 32 additional cases, making 167 cases for consideration.

Of these 32 operations, 13 have been performed in this country, 10 in France, 8 in England, 1 in Germany.

The nature of the foreign body was as follows: In 17 cases the foreign substance was a dental plate: 13 recovered and 4 died: in 6 the substance was a coin; in 3 a stone, of which last cases 2 recovered and 1 died; in 4 a button: in 1 a piece of bone; and in 1 a walnut.

Mortality: Egloff calculated a rate of 24.4 per cent. in the 135 cases at his disposal, and with these additional 32 cases the mortality is now slightly reduced to 22.5 per cent. In the present 32 cases (with 5 deaths), the mortality is diminished to 15.6 per cent. This gain has been due to the facts that the operations have gradually been performed earlier (before the tissues were so much damaged by the prolonged and severe measures first to remove the body through the mouth without an operation) and that the technique also has been much improved. It can be said that the less the tissues are irritated or damaged by manipulation, and the earlier the operation is performed, so much better is the prognosis.

The time which elapses between the accident and the operation is of much importance. In 14 cases in which the operation was performed on or before the third day 3 died (a mortality of 21.4 per cent.). In 7 cases, between the third and the seventh day, 2 died (a mortality of 28.6 per cent.). The shortest period which elapsed was twelve hours; the longest, five years and nine months. Both patients recovered.

The location of the foreign body is also very important. In only 1 case was it lodged above the cricoid; in 17 cases (of which 13 recovered and 4 died) it was either at the level of the cricoid or between that and the top of the sternum; in 11 cases (of which 10 recovered and 1 died) it was behind or near the head of the sternum; in 1 case it was within one and one-half inches of the cardiac end of the œsophagus. In this case œsophagotomy was first performed, and when it was found impossible to extract the dental plate from above, gastrotomy was performed and the plate removed through the stomach incision. In searching the literature on this subject, there have been found 8 cases (see foot note, "Gastrotomy") in which the foreign body was so near the cardiac end of the œsophagus that it was necessary to perform gastrotomy.

Treatment of the wound: In 16 cases the œsophagus was primarily sutured with catgut or silk, the external wound was partially closed, and a gauze drain or tube was inserted down to the sutured wall of the œsophagus. Primary union is stated to have occurred in 2 cases, and it probably occurred in some others, but was not definitely stated. The average time of healing of the œsophagus was seven days, and of the external wound twenty days. In 11 cases no sutures were used, and the wound was drained by gauze packing or a tube: the average duration of healing was twenty-seven days.

Nourishment: In 9 cases none was taken by the mouth during the first forty-eight hours, the nourishment being given by enemata, and none of these cases died; whereas in 12 cases where the nourishment was given from the beginning through the stomach tube, 3 died. In going over the entire 167 cases, one finds that in some cases these details are not given: but in 62 cases where the stomach tube was used from the beginning 40 cases recovered and 22 died, whereas in 38 cases where it was not used, at least not until after forty-eight hours from the operation, the only nourishment being by means of enemata, all recovered.

The cause of death was sepsis in 4 cases, and in 1 case a mediastinal abscess.

GASTROTOMY.

1. Richardson: Boston Medical and Surgical Journal, December 16, 1886. Plate, eleven months; recovered.
2. Thornton: Lancet 1, 1886, p. 57. Mass of hair; recovered.

Wandering Spleens.—In a paper read recently before the Medical Society of London, Bland Sutton (*British Medical Journal*, January 16, 1897, p. 132) maintained that splenectomy for wandering spleen is not only justifiable but also a highly successful operation, the rate of recovery being equal to that of oöphorectomy in skilled hands. He has collected a score of cases thus operated upon within the last twenty years without a death. It has occurred to many that it would be desirable, if it were possible, to secure the spleen in the left hypochondrium by means similar to those for fixing a movable kidney. The results in two reported operations of this kind show clearly that the patients ran much greater risk and had much longer confinement to bed than if the spleens had been removed. The spleen may be regarded as a highly developed and specialized lymph gland, and there seems to be no more reason for hesitating to remove it when "wandering" and troublesome, in so far as remote consequences are concerned, than in excising a chain of enlarged glands. In fact, many if not all individuals with wandering spleen are thin and gaunt, and they retain this character when deprived of this organ.

ON THE REPLACEMENT OF A DEPRESSED FRACTURE OF THE MALAR BONE.[1]

By ROBERT F. WEIR, M.D.,
SURGEON TO THE NEW YORK HOSPITAL.

FRACTURE of the malar bone is not a common injury, and the depression of the broken bone into the antrum is yet more infrequent. From this complication marked deformity ensues, from the flattening of the cheek and from the bony irregularity along the outer part of the inferior margin of the orbit. Disturbance is likewise produced in mastication and other movements of the lower jaw from the compression of the temporal muscle by the zygomal end of the fracture. Its recognition is easy, but the reposition of the displaced bone is usually difficult. The following cases illustrate a method that satisfactorily overcame the deformity, replaced the bone in its normal position, and restored the function of the temporal muscle. The measure adopted in the two instances to be presently detailed consisted in making a small opening with a gouge into the antrum within the mouth, just above the canine teeth, so that through this a No. 12 or 14 (English) sound could be introduced and by this means the depressed fragment forced upward and outward into its proper position. This procedure sufficed in each instance to a very satisfactory degree. The cases in detail are as follows:

CASE I.—Patrick McC——, aged twenty-one years, entered the New York Hospital, October 22, 1890, having been struck six days previously in the face with a heavy mallet, which felled him to the ground and left him for a time unconscious. When admitted to the hospital he was in good general condition, with his right eye nearly closed by an ecchymotic swelling, which invaded also the cheek. A depression existed not only in the region of the malar eminence, but also along the outer part of the inferior margin of the orbit and at the anterior extremity of the zygoma. A sharp projection of bone could be felt just beneath the skin where the fracture terminated in the orbit. He was treated by local applications but suffered from the pain in the upper jaw, with, however, but little in mastication. He came under my observation about three weeks after the injury. The deformity from the difference in the two sides of the face was very pronounced and disagreeable.

Under ether, November 16th, an incision was made through the mucous membrane, just above and to the outside of the right upper canine tooth and the antrum opened by a small gouge. Through this opening a steel sound was passed and with but moderate force the depressed bone was loosened and raised into its proper place. Though it seemed firmly held in its normal situation, it was thought best to retain it by packing the antrum with a long strip of iodoform gauze. This was withdrawn on the fourth day after the operation and replaced, and finally withdrawn on the tenth day. One week later he was discharged, the little wound in the mouth healed, contour of face natural, function of mastication perfect, and only a slight irregularity along the orbit, to be felt but not seen. When inspected several months later the restoration remained equally satisfactory.

CASE II.—Charles K——, aged thirty-one years, was struck by a flying hammer June 1, 1896, receiving a simple fracture of the left malar bone. Two weeks later he entered the New York Hospital. Besides the sunken appearance presented by the left side of his face, there was inability to open the mouth more than three-eighths of an inch. Above the left alveolar margin of the upper jaw, a piece of broken bone or tooth protruded, covered by mucous membrane. Under ether the attachment of the upper lip and cheek to the left superior maxilla was divided and the soft parts were reflected upward until the line of fracture appeared. The malar bone had been crushed down into the antrum of Highmore. No marked irregularity existed along the orbital margin. A urethral sound was passed through the incision under the lower edge of the fractured bone, and the displaced fragment was pried up into position. The antrum was tightly packed with iodoform gauze, which served to hold the malar bone in its correct position and acted as a drain. There was no reaction and four days later the patient was discharged, but the gauze was not finally withdrawn until ten days later. He was seen several months later and the shape of his face was fully restored. In this case, after the malar bone had been replaced, it was found to be so mobile, and to have carried with it a large flake of the anterior wall of the antrum, that difficulty was anticipated in being able to maintain the replaced fragment in good position, but a firm packing of gauze accomplished the purpose.

THE DISPENSARIES OF NEW YORK CITY; THEIR USE AND ABUSE.[1]

By WALTER BROOKS BROUNER, A.B., M.D.
NEW YORK.

THE statistics herein presented, originally gathered to satisfy my own curiosity as to the number of persons annually treated in our city, and to contrast from a numerical standpoint the work done in our various institutions, showed such stupendous aggregates, and the deductions thereof were of such interest to me, that I have ventured to make my investigation the subject of a paper, which I present for your thoughtful consideration to-night. It would seem almost a work of supererogation on my part to revive the moot question of the use and abuse of dispensaries, yet when we read the statistics and ponder well upon their significance, one cannot fail to recognize the possibilities of good accomplished and of evil done—the latter to the profession and laity alike; for surely when in one year more people than the combined populations of Arizona, Colorado, Delaware, Illinois, Maine, Nevada, Wyoming, and Vermont were treated practically free, there must have been many unworthy recipients of one of the grandest and noblest charities of Christian civilization.

The statistics presented were obtained from the last annual report, or, if no report was issued, from those who had charge of the work in the various institutions. The table shows 44 institutions which treated individually patients varying in number from 84,647 to 1,326.

As will be seen by glancing at the table, these 44 institutions treated 707,058 patients, who made in all 2,026,360 [2] visits (being an average of less than 3 visits to each patient), for whom the large number of 1,039,632 prescriptions were filled; for which a fee, ranging from ten to twenty-five cents, was charged in the vast majority of cases in all of the 44 institutions, excepting those under the department of charities and the North Western Dispensary. The 5 dispensaries treating the largest number of new patients were in the order mentioned: Good Samaritan, 84,647; New York Dispensary, 52,109; Bellevue Out-Patient Department, 48,932; Vanderbilt Clinic, 46,449; North Western Dispensary, 40,390.

The 5 dispensaries having the largest number of visits made by these same patients were: Vanderbilt,

[1] Read before the Society of the Alumni of St. Luke's Hospital, New York City, November 10, 1896.

[2] Approximate at the rate of three visits to each new patient, judged from statistics obtainable.

145,305; an average of 3.1 visits made by each patient. Good Samaritan, 138,683; average, 1.6. New York Dispensary, 135,361; average, 2.5. North Western Dispensary, 121,170; average, 3. Bellevue Out-Patient Department, 93,434; average, 1.9.

Of the 44 institutions 12 treated 20,000 or over; 5 treated 15,000 or over; 8 treated 10,000 or over; 5 treated 5,000 or over; the remainder treated less than 5,000.

Another item of interest is to note the distribution of the 715,764 new patients treated: 147,266 were as now most of our hospitals have adopted a practically uniform method in their annual reports.

The following item may be of passing interest to those who are actually engaged in dispensary work. These statistics relate only to those institutions doing a general and not a special dispensary work. The largest surgical service was at the Hudson Street House of Relief: medical, Good Samaritan: orthopædic, Vanderbilt; women's and children's, Good Samaritan; eye, ear, throat, and nose, Vanderbilt; nerve, Vanderbilt; venereal, Bellevue; vaccination, Good

† Hospital and dispensary reports not separate.

medical cases; 110,242 were eye, ear, throat, and nose cases; 90,184 were surgical cases; 105,626 were children's and women's disease cases; 31,304 were skin and venereal cases; 7,013 were nerve cases; 1,055 were orthopædic cases. The remainder were divided between vaccinations, district visits, and dental cases. Surely a marvellous array!

Right here I might state that these figures do not begin to show the real aggregate, inasmuch as many institutions in making up their reports fail to classify their cases. The writer suggests that it might be a good idea if all our dispensaries would, so far as possible, adopt a uniform system of reports in the future; just

Samaritan; largest number of district visits, North Western Dispensary; largest dental practice, Good Samaritan.

This in a general way gives one an idea of dispensary work in New York City for the year 1895; yet you will notice that even this list is but partial, for it does not include the large number of private dispensaries, nor the smaller dispensaries connected with church work, nor does the table include the work done by homœopathic, eclectic, or other institutions. These statistics compare favorably with London and its dispensaries, as shown by the following:

"The London hospitals treat about 87,000 in-

patients and about 1,299,000 out-patients every year. This does not include the large number of out-patients who are treated in the free dispensaries. Besides the 92 voluntary hospitals in London, there are 39 charitable dispensaries, and these in 1895 dealt with 205,833 new cases. Further, there are in London 26 poor-law infirmaries, which deal with about 10,500 patients daily, apart from the inmates in the sick wards of workhouses; and in the course of the year more than 130,000 'permanent,' 'ordinary,' and 'midwifery' medical orders are issued in connection with 44 poor-law dispensaries."

Did time and space permit, we should like to show the per capita cost to each institution for patients treated; *e.g.*, one institution made it a matter of record that the per capita cost for treating over 23,000 patients was less than one-half cent. One thing that struck us as being worthy of note, was the fact that even in the poorest and most densely populated districts, dispensary patients were charged the same for medicine as those visiting the more favored and better-equipped institutions.

Having now disposed of that part of our subject relative to the use of our dispensaries, we come now to the other side of the question—a question of great moment, of vital interest to the profession, a question which some day may occupy the attention of metropolitan physicians to the exclusion of all others, inasmuch as on the proper solution of it depend the chances for a livelihood of many worthy men—namely, the abuse of our dispensaries.

Are Dispensaries Abused?—In gathering the statistics of the various institutions, most of which I visited personally, I was surprised to find the large number of men officially connected with the same who upon being questioned in regard to their individual experience were unanimous in the view that a large part of those treated free were well able to pay a doctor a moderate fee: indeed, in one of the so-called poor institutions, I was told that on a conservative estimate at least forty per cent. of those treated were able to pay a doctor. Indeed, it is not a novel experience for one to meet at the theatre or out riding on a wheel the very patients who were too poor, forsooth, to pay a doctor, and hence availed themselves of dispensary treatment. In the clinic in which I am an assistant, it is not an unusual thing for men to ask if their urethral or prostatic trouble would be aggravated by the use of a bicycle; indeed, one patient had the temerity to ask me if horseback riding was likely to prove injurious! And so I might go on citing instances *ad infinitum*.

What Constitutes Ability to Pay a Moderate Fee?—Herein lies the stumbling-block to a proper solution of the question of dispensary abuse. It is absolutely impossible to tell from the look of a toad how far it can leap; so with our dispensary patient, we cannot judge from external appearances the deserving from the undeserving. Yet from a large experience, a series of cross-questioning, etc., I have come to the conclusion that the number of those who really can afford to pay a small fee is legion (by small fee, I mean $1). When we consider that most patients have to pay car fare, that as seen in my statistics (excluding Bellevue and the North Western Dispensary) at least ninety per cent. of the patients pay for their medicine in sums ranging from ten to twenty-five cents, and when we consider that a large proportion of the men—and women, too—is losing time and pay for absence from work, it is evident that many dispensary patients delude themselves: for they are really expending more than it would cost to pay a private doctor.

Who is Responsible for the Abuse?—It must be said on behalf of the people that they in a measure are not to blame; they are human—no more, no less. Who would not accept a free annual pass for the theatre, or for the elevated railroads, if they were as easily obtained as dispensary treatment, with practically no restrictions—simply to be had by the mere asking? The comparison is not overdrawn a bit. When we as physicians begin to recognize that our services are as much a commodity (having a fixed value) as anything offered in the market: when we as clinical assistants look upon the unworthy clinical patient in the same light as the deadbeat, who sometimes—alas, too often—is found in the "profit and loss" column of our ledgers; and when we give them their just deserts—then perhaps our responsibility for the abuse will not be so large as it is now.

It seems to me that the object for which most of our charitable institutions was founded—namely, the relief of the worthy sick poor—has been lost sight of, so that to-day all are admitted alike: it is simply a case of asking and receiving. In gathering the statistics herein presented, which involved an enormous amount of reading, I can recall only one institution which gave the number of patients refused treatment because of their ability to pay. In short, on ultimate analysis the responsibility for the abuse is evident. The institutions themselves are to blame, and, incidentally, the men who like myself give their services in a cause so unnecessarily abused—a cause which in a measure accounts for the dearth of private practice. Think of it; if a doctor attend a clinic three times a week for fifty-two weeks, treating daily on an average five patients, every one of whom could pay a moderate fee, say $1 (yet this is a small average), what has he done? Simply deprived the profession of $780 in one year. It does not take much of an arithmetician to estimate the net result of a year of such work. If we suppose that twenty-five per cent. of the two million and odd visits made by patients at dispensaries had been paid for in our offices instead, at the small sum of $1 per capita, $500,000 would have been placed to the credit of the profession. This means that if five hundred doctors of New York City had gotten an even share of the work, each would have had to his credit in the bank $1,000 for the year 1890!

How Can We Remedy the Abuse?—As has already been stated, there are at present no deterrent factors at work to discourage this evil practice: just so long as our dispensaries are open freely to all comers, just so long will the abuse continue. My suggestion is that, commencing with the year 1897, all institutions inaugurate a thorough and systematic effort to separate the worthy from the unworthy, after the following plan. Let each applicant for dispensary treatment be registered on a card, giving name, age, exact address, occupation, salary, and the number of those dependent on applicant for support. For this registration a small fee should be charged. Let all applications be investigated by a paid corps of inspectors, whose salaries could be paid out of the registration-fee fund; the reports to be submitted by the inspector to the clerk of the dispensary should state the inspector's opinion as to the worthiness of the applicant, based upon the truthfulness of the applicant's statement, environment, etc. As soon as the case had been passed upon, a printed notice could be mailed by the clerk in a sealed envelope, stating that upon suitable investigation the individual had proven worthy or unworthy. For example:

Mr. John Jones applies to-day, Tuesday, the 10th, for treatment, between 1 and 2 P.M., having filled out the application. At 3 P.M. the card is given to the inspector, who looks up Jones and submits his report on the same within twenty-four hours. On the day following the application the result of the investigation is mailed to the applicant, so that by Thursday, the 12th,

Mr. Jones knows the result at an hour early enough to permit him being treated that day at 2 P.M.

Against such a system it will be urged:

1st. That many will be unable to pay a registration fee; for such, let the registration be free and the cases investigated nevertheless.

2d. That acute or emergency cases might be neglected. The same rule could apply—let the case be treated at once and likewise investigated.

3d. That such a system of inspection would not be feasible. The fact is, few institutions average one hundred new cases a day; it would be a simple matter for four inspectors to do all the work.

The advantages claimed for such a system of registration are:

1st. That as soon as the people know of it, there will be a marked falling off in new patients; for then only those who truly are needy and deserving will apply.

2d. The people will realize, what they do not now realize, that dispensaries are intended only for the sick and worthy poor.

3d. After the registration system is thoroughly established it will be possible for each institution to work within certain city limits, thus conforming more to the local dispensary plan: *e.g.*, a Harlem patient applying at a down-town institution would be referred to an institution in Harlem.

4th. It would do away with the large out-of-town contingent, most of whom are fully able to pay a doctor.

5th. It would minimize the baneful effects on the masses, who are led into the temptation of accepting what is not lawfully theirs; it would substitute thrift for indolence, independence for dependence, honesty for dishonesty.

And, lastly, it would make possible what is now for many New York physicians an impossibility, viz., a comfortable livelihood, derived from the "Simon-pure," old-fashioned, time-honored, private practice.

256 West Twelfth Street.

IMPROVED TECHNIQUE OF VAGINAL LIGATION OF THE UTERINE ARTERIES FOR UTERINE FIBROMATA. INDICATIONS FOR THE OPERATION.[1]

By AUGUSTIN H. GOELET, M.D.,

Professor of Gynæcology in the New York School of Clinical Medicine, etc.

The purpose of this operation, which was suggested and executed first by Martin in this country and by Gottschalk in Europe, in 1892, is to produce atrophy of the tumor by cutting off the nourishment afforded by the uterine arteries which furnish the uterus with two-thirds of its blood supply. The operation has not received the attention and consideration it deserves as a conservative surgical measure, because the results were not perhaps in every instance what were anticipated or promised for it. Failure to obtain results with any new operation is usually due to misapplication or to a faulty technique. It is certainly true that some operators (Martin for one) have obtained from this operation a fair measure of success, sufficient to induce them to repeat it in certain carefully selected cases. From my own experience I am inclined to believe that it has a place in gynæcological surgery, and when it has failed the circulation has probably not been permanently cut off, because the vessels have not been completely and permanently obliterated, or its indications have not been clearly understood. Some operators have declined to try it, and others, after a few attempts, have apparently abandoned it before giving it a fair trial, in favor of hysterectomy, the mortality of which has been reduced by improved technique and a more extended experience to a point where it is now regarded as a justifiable procedure. But we must not lose sight of the fact that this latter is a radical operation, which, while it unquestionably removes the tumor *in toto*, unsexes the patient. It is true that in some cases this cannot be avoided, but when it can be avoided it should be.

To convey some idea of the inefficient manner in which ligation of the uterine arteries has been executed by some operators, I will say that several with whom I have conversed have admitted that they have passed the ligature without incising the vagina or attempting to isolate the vessels. This will explain some failures. One operator informed me that his method was to feel for the pulsation of the artery; then a curved needle with a catgut ligature was passed up through the vaginal wall in front and around, then brought out behind the vessel, and then tied, including a portion of the vaginal wall. At best, if the vessel happened to be included in the ligature, this would cause only temporary compression, and the circulation would be restored when the ligature loosened.

Martin believes that it is essential to include the tissues of the base of the broad ligament, the nerves as well as the blood-vessel, in order to destroy the function of the nerve supply. By including these tissues with the artery in the ligature, permanent obliteration of the vessel is by no means certain; as a fact, it is very uncertain. When the ligature is first tied, with other tissue surrounding the vessel included with it, the circulation may undoubtedly be temporarily arrested, but permanent obliteration of the artery is not necessarily secured. As the included tissue shrinks from compression of the ligature, it loosens, and if the coats of the artery have not been ruptured the circulation is restored. Hence it is evident that positive and permanent obliteration of the artery can be secured only by carefully isolating it and tying it separately, or tying it with the tissues at the base of the broad ligament *en masse* and dividing it. As this artery will bleed from both ends, owing to the free anastomosis with the ovarian artery, it is necessary to apply two ligatures and divide between them. I contend, therefore, that in order positively to secure complete obliteration of these arteries it is necessary to divide them. In doing so, the nerves at the base of the broad ligament are also divided if this is important.

My observations bear me out in this conviction, since my best results have been obtained when this method was adopted. I have, of course, been careful to select my cases, and have employed the operation only in interstitial growths which have not reached above the level of the umbilicus and small subperitoneal growths which spring from the wall of the uterus below the fundus, and when extensive adhesions have not formed through which the tumor might receive nourishment. Subperitoneal tumors attached at or near the fundus would receive their nourishment from the ovarian arteries, and cutting off the blood supply of the uterine arteries could not be expected to influence their nutrition.

The temporary improvement in some of Martin's reported cases would go to show that with his method of ligation *en masse* without division of the vessels he only secured temporary arrest of the circulation.

In order more clearly to comprehend the nature of this operation, let us recall the anatomy of the uterine blood supply and the relation of the ureters, which are in such close proximity to the field of operation that they are in danger of being wounded. The uterine arteries, springing from the anterior division of the

[1] Read at a meeting of the New York State Medical Society at Albany, January 26–28, 1897.

internal iliac, pass inward along the vaginal vault on either side until they reach the sides of the uterus about on a level with the internal os. Here they take a sharp turn upward along the side of the uterus and meet the ovarian arteries, with which they are continuous. There is, therefore, a free anastomosis between the uterine and ovarian arteries. Several small branches are given off from the uterine arteries before they reach the uterus, which supply the cervix and the upper part of the vagina. The cervix is likewise supplied with blood by the azygos artery of the vagina, which empties into the circular artery of the cervix.

The pelvic portion of the ureters lies close to the pelvic wall in the first part of their course. At first they diverge on entering the lesser pelvis, then converge in their course downward, crossing behind the uterine arteries about on a level with the internal os, at which point they are from one-half to three-quarters of an inch from the side of the uterus. This distance is nearly constant. They then converge still more in their course along the anterior vaginal wall until they reach the point where they enter the bladder, where they are two inches apart.

Technique of the Operation.—The patient is prepared as for a vaginal hysterectomy, the vulva being rendered absolutely aseptic by shaving and scrubbing with softsoap, and irrigation with lysol or bichloride solution. She is anæsthetized and placed on the table in the exaggerated lithotomy position, with the buttocks near the edge of the table. A short broad perineal retractor is inserted in the vagina and held by the nurse, who sits to the left of the operator. A traction ligature is now inserted through both lips of the cervix, and the uterus and canal of the cervix are carefully curetted, then irrigated with a one-per-cent. solution of lysol, and packed with iodoform gauze.

The exact manner of exposing the base of the broad ligaments with the uterine arteries will vary with the condition found. If the tumor is of moderate size and the arteries have not become misplaced by the position of the tumor, a lateral incision through the vaginal wall, entering at the utero-vaginal fold, will be sufficient to enable the operator to secure the vessel without difficulty. But if the tumor is large or the arteries do not occupy the usual position, it will be necessary to have more room for comfortable work, and in these cases I have employed with satisfaction the incision demonstrated by Ségund as the first step in vaginal hysterectomy, which affords more room. This incision is made as follows, viz.: the cervix is drawn down and with a scalpel a longitudinal incision through the mucous membrane is made on each side of the cervix, beginning near the external os and terminating a little to the outer side of the cervico-vaginal fold. These incisions are now joined by another through the mucous membrane across the front of the cervix and behind. Drawing the uterus down by traction upon the ligature, the mucous membrane is dissected back with the thumbnail all around to a little beyond the cervico-vaginal fold. This gives a larger and freer field for work and facilitates finding the vessels when the position of the tumor has distorted their course.

From this point on the technique is practically the same in all cases. The vaginal wall being penetrated and the base of the broad ligament exposed by either method, the uterus is drawn down and over to the right, so as to put first the left broad ligament on the stretch. With the index fingers inserted in the anterior angle of the wound, the bladder is carefully separated from the broad ligament and the ureter is pushed to one side. At the posterior angle of the incision the broad ligament is freed behind in a similar manner, without penetrating the peritoneal cavity. If now a traction ligature is inserted in the lateral flap of the vaginal incision, it will facilitate the subsequent steps of the operation. The broad ligament is now grasped with a pair of clamp forceps close to the side of the uterus and between it and the ureter, which at this point is half an inch or more away from the uterus. A strong catgut or silk ligature is now carried through the tissues of the broad ligament outside of the clamp, from before backward, by means of an aneurism needle. This ligature is tightly tied close to the clamp. The tissues between the clamp and the uterus are then divided with the scissors, and the severed uterine end of the artery is picked up with the pressure clamp and tied. The clamp is now removed, the wound is irrigated with lysol solution, and the vaginal incision is closed by continuous catgut suture. The vaginal wound is dressed with markasol gauze, which is removed after forty-eight hours, and thereafter every twenty-four hours until union is complete, which will usually take place in from four to six days. The gauze is removed from the uterus at the end of forty-eight hours, when the cavity is freely irrigated with one-per-cent. solution of markasol and the packing is removed or not, as required. Usually it is not replaced in the uterus. After removing the gauze dressing permanently the vagina is irrigated daily with one-per-cent. solution of markasol This is preferred for vaginal irrigation, because it is antiseptic and moderately astringent without being irritating.

One operator had sloughing of the cervix follow ligation of the uterine arteries in three of his cases, which led him to abandon it. I have never had such a result, and think it must have been due to a faulty technique, perhaps too extensive dissection and unnecessary mutilation. When the lateral incision is employed, the nutrition of the cervix is not materially interfered with by cutting off the supply of the uterine arteries, since the azygos artery of the vagina would afford sufficient blood supply.

The apprehension that obliteration of the uterine arteries may result in gangrene of the uterine tissue is entirely unfounded, since sufficient nutrition is always afforded by the ovarian arteries. It has been reported that no such result followed ligation of both uterine and ovarian arteries, showing that the supply furnished by the small arteries of the round ligaments is sufficient.

Likewise the objection raised by one surgeon, in a recent discussion before the New York Obstetrical Society, that there is not sufficient space between the ureter and the side of the uterus to apply two ligatures and cut between them, is not justified, in the face of the fact that it has been done repeatedly. By drawing the uterus down to one side, this space is increased, and the ureter is pushed considerably to one side in the preceding steps of the operation and held there by means of a lateral retractor.

While this operation has only a limited application in fibroid conditions of the uterus, it possesses some advantages which commend it, viz.:

1. It involves little or no risk when carefully executed.
2. It does not involve a tedious convalescence.
3. It is quickly and easily performed.
4. Its immediate result is to afford prompt relief of the symptoms.
5. Its ultimate result, which is manifest within six months, is complete or almost complete atrophy of the tumor.
6. It does not unsex, mutilate, or disable the patient.

Oklahoma has one physician to each two hundred of population.

Progress of Medical Science.

Associated Movements in Paralyzed and in Unparalyzed Idiotic Children.—At a recent meeting of the Berlin Society for Psychiatry and Nervous Diseases, Koenig (*Berliner klinische Wochenschrift*, January 4, 1897, p. 17) detailed the results of a study of forty-six cases of cerebral palsy of various kinds in children and of thirty-eight cases of unparalyzed idiotic children of from seven to twenty-one years of age, undertaken for the purpose of determining the frequency and distribution of associated movements. He classified these movements into four varieties: (1) Typical or corresponding associated movements, viz., involving the same muscles of symmetric parts; (2) irregular corresponding movements associated, viz., involving symmetric parts, but not the same muscles; (3) atypical associated movements, viz., involving indifferent and not corresponding muscles; (4) reflex associated movements, viz., those induced by peripheral irritation. It was found that associated movements were not present in fifteen per cent. of the paralyzed and in thirty-four per cent. of the unparalyzed children. All varieties of associated movements observed in the paralyzed, with the exception of the reflex, were present also in the unparalyzed. The most conspicuous difference between the two sets of cases was that the associated movements were more common, more pronounced, and less under the influence of the will and of training in the paralyzed than in the unparalyzed. The associated movements were not characteristic of any special form of cerebral infantile palsy, although it appeared that among cases of pure hemiplegia those in which associated movements occurred as well with movements of the paralyzed fingers as with those of the unparalyzed fingers preponderated over those in which the associated movements occurred only on one side of the body. The well-known fact was confirmed that the associated movements in the fingers were those that are most seldom absent and are of the greatest importance. From a pathologico-anatomic point of view it was found that associated movements attend lesions of the cortex as well as those of the basal ganglia. Movements were also observed in conjunction with disease of the pyramidal tracts, as well as in the absence of such lesions. Associated movements were noted in idiots up to the age of eighteen years. In three beyond this age they were not observed, possibly from accidental circumstances. No rule could be formulated for the frequency of associated movements in the unparalyzed idiots with relation to age.

The Influence of Constitutional Disturbances upon the Teeth.—At a recent meeting of the Berlin Society for Internal Medicine, Neumann (*Berliner klinische Wochenschrift*, January 4, 1897, p. 14) discussed the influence exerted by constitutional diseases upon the state of the teeth. He pointed out that rachitic erosions occur symmetrically upon different teeth at varying levels through interference with the process of calcification. The deciduous teeth may also be eroded, but only at the same places as the permanent teeth. The erosions may in some instances begin before birth, but as a rule they take place during the first five months of life. The morbid process on which they depend terminates in fifty-four per cent. of cases in the second half of the first year of life, in thirty-eight per cent. in the second year, and in six per cent. at a later period. Many theories have been invoked to explain these erosions, but none is adequate. The lesions occur as the result of a morbid process continuing at least for several months and frequently longer. They bear no relation to syphilis and are dependent exclusively upon rachitis, and upon that special form involving the bones of the head. They are exceedingly common, being found on the permanent teeth in eighteen per cent. of children and on the teeth of fifty-four per cent. of children dying during the second half of the first year of life. The teeth peculiar to hereditary syphilis differ from rachitic teeth in the disease not being local, but consisting in a malformation of the entire tooth. The impression that only the upper median incisors are affected is not correct. Such teeth are characterized by standing far apart, by being rotated on their axes, by standing in divergent relations with each other and by malformation of the crown. They are not common. The malformation occurs between the seventh month of fœtal life and from the third to the fifth month of extra-uterine existence. It does not involve the deciduous teeth, because the rudiments of these are formed at a time when syphilis of the fœtus usually results in abortion. The common form of caries begins on the incisor and gradually invades the surface of the entire tooth. It bears no relation to rachitis. It reaches its maximum of development during the second year. It is often observed in connection with chronic disease of the nervous system, especially idiocy. Circular caries is characterized by early discoloration of the teeth at the gingival margin. Caries of the neck takes place and progresses deeply until the distal extremity of the tooth is cut off, leaving an unrecognizable root. It occurs in connection with grave disease, especially tuberculosis, of which it is diagnostic.

Syphilitic Disease of the Heart Wall.—From a clinico-pathologic study, Phillips (*Lancet*, January 23, 1897, p. 223) concludes that syphilis may give rise to the formation of gummata or the production of general fibroid changes in the wall of the heart. Gummata of the left ventricle, unless of very small size, are dangerous to life, and when near the apex of the ventricle may cause sudden death. Such gummata may be suspected if in an individual with syphilitic antecedents there occur signs of derangement of the action of the left ventricle, with symptoms of embarrassed action, especially angina pectoris, tachycardia, syncopal or epileptiform attacks; or in the right ventricle when dyspnœa, otherwise unaccountable, occurs. Extreme feebleness of the heart, without dilatation, gradually increasing in young or middle-aged persons who have had syphilis, suggests syphilitic disease of the left side of the heart; and long-standing dyspnœa may point to similar disease of the right side of the heart. Dilatation of either side of the heart in syphilitic persons may result from syphilitic fibrosis. Hypertrophy of the heart, without ascertainable cause and without corresponding increase in strength of heart, suggests syphilis. Aneurism of the heart wall may result from syphilitic local lesions and may be fatal, with or without rupture. It is probable that gummata and fibroid disease in early stages may be relieved by the usual specific treatment, and there is every reason to believe that syphilitic lesions of the heart wall are not less amenable to treatment in their early stages than syphilitic lesions elsewhere, though no cure can be expected when advanced tissue changes are already produced. Syphilitic disease of the heart is probably more common than is generally recognized. Its importance is the greater because it affects persons at an earlier age than the usual degenerative conditions of the heart, and may insidiously advance until it causes sudden death in persons in the prime of life and apparently in perfect health. The existence of syphilitic affections of the heart cannot be without influence on the action of anæsthetics.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, March 6, 1897.

SEVERE VOMITING DURING PREGNANCY.

To this subject Grailly Hewitt has given special attention, having collected records of a hundred cases and adding much valuable matter in an essay. He urges that a proper distinction be made between the vomiting of pregnancy which is produced by and directly dependent upon the condition itself, and vomiting occurring during pregnancy yet due to diseases or causes not connected with the pregnant state. In twenty-four cases recorded the severe vomiting was found to have for its origin one of the following abnormities: chronic gastritis, gastro-enteritis, cancer of the pylorus, carcinoma of the liver, biliary calculi, fatty degeneration of the liver, pulmonary and cerebral tuberculosis, polypoid disease of the intestines, etc. These cases of severe vomiti g all resulted in death, and the post-mortem examinations revealed the fact that definite lesions existed causing the distressing condition, that was not directly due to the physiological process that was going on. The cause of death in a case reported by Matthews Duncan is set down as icterus gravis, formerly called yellow atrophy of the liver. This, Hewitt remarks, is an important record, since it has been made the basis of a generalization on the vomiting of pregnancy, Duncan stating in his book on diseases of women that in healthy pregnancy the first stage of this disease occurs. According to physiologists, the great glands of the body, the liver and the kidneys, especially the liver, undergo in healthy pregnancy and lactation a certain amount of parenchymatous degeneration, almost identical with the first stage of Bright's disease and acute yellow atrophy of the liver. As this change proceeds farther in the kidneys or the liver, eclampsia or pernicious vomiting results. Bile retention alone is hardly sufficient to give rise to the serious complications observed in the grave forms of catarrhal icterus affecting pregnant women, in which convulsions, severe vomiting, and hemorrhage may occur. Somer suggests that altered nutrition changes peculiar to the situation, resulting in special susceptibility to poisons, give the true explanation. Biliary acids retained in the blood, like phosphorus, are capable of producing disintegration of the blood corpuscles. This same icterus gravis occurs in men and women alike; but it is unusually fatal in pregnant women, for the foregoing reasons.

In the majority of cases in which severe vomiting marks a process that should be purely physiological and without disaster, there are usually present abnormal conditions in or about the uterus. There may be displacements, or induration, thickening, contraction of the cervix, or inflammatory effusions in the vicinity of the uterus. Relief of these abnormities usually stops the vomiting. In other instances induced abortion is the only cure. Even this is at times inefficacious, so profound is the exhaustion induced by the previous chronic starvation. Innumerable drugs have been recommended, most of them quite useless in severe cases. Those likely to be of service are sedatives—cocaine, opium, and the bromides. Local medication is of benefit in some instances. Vaginal tampons saturated in poppy decoction are of great use; also cocaine applied to the os or to the interior of the cervical canal, and caustic applications. Hot douches not too frequent, and rectal suppositories containing opium, morphine, belladonna, or hyoscyamus, suggest themselves as valuable aids. The administration of food is of great importance. Sometimes the stomach will retain nourishment given in minute quantities and at frequent intervals. In certain cases starvation can be prevented for a time by the systematic use of suppositories containing nutrient substances. Each case must be dealt with on its merits. Good food, nerve tonics, fresh air, and general hygienic measures may give relief when the trouble is not severe. Rest in fair amount Hewitt insists upon, and the horizontal position, maintained in varying degree of strictness, is essential in all cases.

ARE THE BRITISH DEGENERATING?

A NOTE of warning has recently been sounded in England concerning the danger to the physical strength of the nation of cherishing unduly the sick and the feeble. The occasion of the protest, which was uttered by Mr. Arnold White, was the proposal to celebrate the rounding out of sixty years of Queen Victoria's reign by the establishment of many new nursing-homes for the extension of hospital work among the poor. Mr. White would not go to the Spartan length of making way with incurables and the congenitally unfit, but he thinks it is time to do something to prevent their multiplication. Too little, he thinks, is done to improve the physical condition of the well, and too much to bring up the weak and the diseased to a state in which they will be just able to procreate their kind. "What is aimed at," he says, "is not the murder or neglect of the sufferers who have entered the world, but to obtain partial control over the supply of suffering."

Some have thought that the immense standing armies are a direct menace to the future of the nations of continental Europe, since compulsory service withdraws from the business of procreation large numbers of the strongest and physically most perfect men, at an age too when they are most fit for fatherhood, leaving behind the smaller and the weaker to beget future citizens. But Mr. White thinks otherwise. "The

marked improvement," he says, "in the physique of the French and German people since their adoption of a compulsory military service is so remarkable that even the English hospital authorities might well ponder over the deterioration of fibre among certain classes of their own country. Thirty years ago the French were regarded as monkeys or satyrs. Now they are men. The French soldiers of 1896 are vastly superior to their fathers of 1870. Foreign generals note the contrast between the physical renaissance of the continental nations and the fool's paradise in which England basks. Our separate caste of fighting men, our cult of sickliness and worship of weakness, our heedless conversion of the rural population into pasty-faced townsmen, and our cheerful dependence on the food produced by healthy races and possible enemies, are matters that are watched abroad with delighted surprise."

It is unquestionably true that the softened conditions of modern life and recent discoveries in medicine and hygiene have led to the prolongation of many lives which, from the stock breeders' point of view, are of doubtful value. But the same factors have also carried untold numbers of the well and strong over periods of danger and stress, which in former ages they would not have survived. And so the account is even, or, despite Mr. White's gloomy view, rather on the side of a physical betterment of the human race, including, we would fain believe, that portion of it which peoples the British Isles.

THE CHARITY ABUSE.

To such as are interested in the study of the present status of medical charity there is much in this issue of the RECORD to merit attention. The situation is a serious one when committees of county organizations are appointed to report upon it and when lively discussion in open session is thus invited. The time has come when there should be some very plain talk on the subject. There is a disposition on the part of the lay managers of the hospitals and dispensaries of this city, not only to ignore the protests of the profession regarding the free treatment of patients who can pay, but openly to defy any reasonable effort to remedy an incorrigible outrage. The number of patients treated who are undeserving of charity is simply appalling. Such are taken from the legitimate sources of the younger practitioners' income, formerly small at best, but now barely adequate for decent subsistence. Strange as it may seem, no other profession save that of medicine is expected to give so much of charitable service even to the very poor. The lawyer does not, neither does the clergyman. The former always insists upon a retainer before work is commenced. The guarantee fee is always demanded either from the client or his friends. The clergyman must always be provided with a living salary before he starts on his charitable errands. To the doctor, however, the urgency of human suffering admits of no qualification in its appeal for the necessity of willing and immediate help. Advantage has been taken of the latter condition from the time the good Samaritan attended the notable charity patient of history, and the ever-ready doctor has been the victim of every scheme for the furtherance of all charities true or false. Unconsciously he has become the tool of every corporation that claims to do for the poor. True to the instincts of such lay combinations, there is now being developed a system of monopoly of charity, in which money overvalues medical service and controls the market against every legitimate means to the proper end. Hence we find millions of money put into hospitals that have no use whatever. In proof of this and in spite of enormous donations from duped philanthropists, these institutions become chronic beggars on the community at large in consequence of too much zeal in the charity-booming business. From the managerial point of view it is very gratifying to play philanthropy, even if it is a costly game. The doctors, however, who are the real essentials for this work, are the only persons who suffer. The hospital, when once started, must pay in some way or other. It must show its reason for existence by the large number of cases treated. To expect any discrimination of proper cases on the part of hospital authorities under the circumstances is almost hopeless. The doctors are there for practice and they get it. The managers can smile when they are asked to show fair play to the men who do all the work. The hospital must pay as a business investment if possible. Hence private rooms are fitted up, the public is invited to see them, and is educated to believe that medical or surgical treatment is the only thing to be obtained free and without question. Doctors are apparently too plenty to quarrel about extra privileges. If one staff resigns, there is another with hat in hand, ready for the vacancy. So the managers boss the situation and table all resolutions of protest. What is wanted is concerted action by the doctors. If the medical attendants were to refuse treatment to improper cases or resign, and if the places could not be filled by respectable men, most if not all the hospitals would be compelled to close their doors. But then what would the diamond dispensary of the West Side do for its clinical material and the one-dollar dispensary of the New York Hospital do for its much needed income? And what, too, would become of the poor doctors who must hold their places in these clinics? The managers understand the situation perfectly, and smile complacently while the suffering doctors discuss, resolve, and protest. "The doctors protest! Good gracious! what business is it of theirs?" say the managers.

AN HONEST CONFESSION.

THE editor of one of our esteemed contemporaries in a Western city, commenting upon certain unethical modes of advertising in practice among his colleagues, and for which they were taken severely to task by a speaker at a meeting of one of the local medical societies, remarked, with all the evidences of real contrition:

"To the charge of having one's name placed in a hotel directory we ourselves must plead guilty, but, hav-

ing as we believe a strict regard for the code and all its principles, it was only after being assured by the solicitor for this directory that some of the most prominent of the older members of the local profession—whom we regarded as ethical models—had subscribed to the scheme, that we consented to permit our name to be used. But

> "'To wilful men
> The injuries that they themselves procure
> Must be their schoolmasters,'

and now we wish we had back our three dollars. All of this advertising is wrong, very wrong. It is degrading to professional standing, and indeed is, we believe, more to the detriment than to the good of the advertisers."

This has the right ring. It is true repentance. The confession is honest and manly. We rejoice while we chronicle it, and it leads us to hope even yet for the conversion of fifteen Chicago physicians, whose portraits and biographies appeared in the *Inter Ocean* last summer, just after their return from Atlanta. There were many other professional advertisements on the same page, of chiropodists, gynecologists, genito-urinary specialists, catarrh specialists, and others. But these were small and inconspicuous, and not illustrated; so the subjects of them did less violence to the code of ethics. Moreover, the latter were pariahs anyway, and repentance would do them no good: but we doubt not the American Medical Association would restore the others to good standing if they would but turn back and with true contrition beg forgiveness.

News of the Week.

A Modest Appeal.—The managers of St. Luke's Hospital have issued an appeal, copies of which have been sent to many if not all of the physicians in New York, for contributions of money to enable them to fill their building with patients. The hospital has room for more patients, they say, but the wealthy managers "cannot open the wards at present unoccupied, or begin other departments of service as yet unorganized" (probably a free dispensary for the well-to-do residents of the West Side), without more revenue, to be obtained by "donations of any amount, from $10 upward, renewable annually at pleasure of donor." This appeal to the doctors for financial assistance in the good work of taking care of the doctor's patients is signed by the eight members of the executive committee, representing an aggregate wealth exceeding by many million dollars the total possessions of all the three thousand or more medical practitioners in the city.

The Western Surgical and Gynecological Association.—The sixth annual session of this association was held at Topeka, Kan., December 28 and 29, 1896. General Caldwell delivered an address of welcome on behalf of the State. He took occasion to compliment the medical profession of to-day, and declared that it had accomplished more in the past thirty years than in all previous time. Mayor Fellows, of Topeka, delivered an address of welcome on the part of the city. On Monday evening a banquet was served at the Copeland Hotel. Denver was selected as the next meeting place of the association, and December 28 and 29, 1897, as the time. The following officers were chosen for the ensuing year: *President*, Dr. Joseph Eastman, of Indianapolis, Ind.; *First Vice-President*, Dr. D. S. Fairchild, of Clinton, Iowa; *Second Vice-President*, Dr. B. B. Davis, of Omaha, Neb.; *Secretary and Treasurer*, Dr. Herman E. Pearse, of Kansas City, Mo. Dr. W. W. Grant, of Denver, was chosen chairman of the committee of arrangements.

A New Chapel at Bellevue Hospital.—The Arthur Leary Memorial Chapel at Bellevue Hospital was dedicated on last Saturday forenoon by Archbishop Corrigan. The chapel will be in charge of the Carmellite fathers.

Alexander J. C. Skene, M.D., LL.D.—A cablegram from London states that the senate of the University of Aberdeen has decided to confer the degree of LL.D. upon Professor Skene, of the Long Island Medical College, Brooklyn, N. Y.

Lord Playfair's Medical Qualifications. — The *British Medical Journal* quotes, with disapproval, a paragraph from the MEDICAL RECORD concerning Lord Playfair, in which it was stated that he was a physician. Our information was derived from the London *Medical Press*, which we assumed to be a reliable authority on all matters in which its hatred and ignorance of things American did not come into question. We apologize to Lord Playfair or the British medical profession, whichever party may feel itself the more aggrieved.

Injuries from Football.—*The Lancet* of January 9th gives some interesting notes on football in England. It seems that from December 21st to time of going to press, there were nine players who were severely injured at the game, and out of this number one died and one was lying at the point of death when last heard from.

Quarantine Against the Plague.—Travellers embarking from ports known to be contaminated by the pest can now enter France only at Pauillac, Saint-Nazaire, Havre, and Dunkerque, and then only after a detention of from four to eight days and fumigation of their effects.

Wisconsin's Shame. — Frederick Rutland, who calls himself a doctor and president of the Wisconsin Eclectic Medical College, has been arrested in Chicago by the government officers, on the charge of using the mails to defraud. He has sent out thousands of circulars to druggists and others, offering to furnish medical diplomas upon payment of from $10 to $50. Rutland claims that his college is a regularly chartered corporation under the laws of Wisconsin, and that his proceedings have been regular in every way.

He claims to have "graduated" nine hundred and seven students last year. Wisconsin gave the man a cloak of legality, and Chicago gave him a home, but the United States postal authorities have, we trust, put an end to his nefarious trade.

Obituary Notes.—Dr. John C. Lewis, of Panama, N. Y., died of pneumonia, February 6, 1897, at the age of forty-eight years. He was graduated in medicine from the University of Buffalo in 1874, and had been in active practice in the town of Panama for twenty-two years, where he enjoyed the esteem of his patients as well as of his fellow-members of the Chautauqua County Medical Society.—Dr. Henry K. Huntington died suddenly on Sunday morning at his home on City Island. At one time he was a physician at Hart's Island. Dr. Huntington was fifty-one years old.—Dr. Saturnino M. Jiménez died of pneumonia at his home, 16 West Eighty-fourth Street, on Wednesday, the 18th ult. He was born in Matanzas, Cuba, in 1851. He was graduated from the Jefferson Medical College of Philadelphia in 1878, after which he went to Europe to study. He returned to this country and served as an interne in the Blockley Hospital in Philadelphia, and afterward in the Pennsylvania Hospital. He came to this city to take charge of the practice of Dr. Juan Cisneros, who retired. Dr. Jiménez was an active worker in the Cuban cause.—Dr. John Kirby, for twenty-one years first assistant at the State Hospital for the Insane at Trenton, N. J., died on February 27th, at the age of seventy-one. He was a graduate of the University of Pennsylvania.—Dr. Michael W. A. Wuelfinch died at Reading, Pa., on February 17th, at the age of fifty-one years. He was born in Holland, and was graduated from the University of Amsterdam in 1876. He was a surgeon in the Dutch army for several years, and located in Reading in 1880.—Dr. William R. Little, coroner of Hunterdon County, N. J., died at Phillipsburg, on February 13th, at the age of forty-seven years. He was graduated from Lafayette College in 1873, and from the medical department of the University of Pennsylvania in 1878.—Dr. Henry S. Gross died at Philadelphia on February 21st, at the age of fifty-seven years. He was born in Montgomery County, Pa., a short distance above Collegeville, and was graduated from the medical department of the University of Pennsylvania in 1861. He at once enlisted in the Union army, and became assistant surgeon in the twenty-sixth Pennsylvania regiment, serving until the close of the war.—Dr. J. C. Claudy died at Newville, Pa., on February 20th, at the age of fifty-five years. He was graduated from Bellevue Medical College in 1865, and entered the United States service as surgeon in 1866.—Dr. Eugene K. Mott died at Chester, Pa., on February 22d, at the age of fifty-six years. He was graduated from Jefferson Medical College in 1868.—Dr. William B. Henderson, one of the oldest physicians of Dauphin County, died at Steelton, Pa., on February 22d. He was a graduate of the medical department of the University of Pennsylvania, and during the war served in the Union army as a surgeon.

Lancaster (Pa.) City and County Medical Society.—The fifty-second annual reunion of the Lancaster City and County Medical Society was held on February 17th, a large number of invited guests from other cities being present. Dr. Alexander Craig, of Columbia, acted as toastmaster, and the following toasts were responded to: "The State Medical Society," by Dr. E. E. Montgomery; "Microbes," by Dr. John B. Roberts; "Medical Education," by Dr. H. A. Hare; "The Family Doctor," by Dr. J. L. Ziegler, of Mt. Joy.

A Doctor Convicted of Murder.—Dr. Thomas L. Johnston, of Duncannon, Pa., who killed a druggist in September of last year through jealousy, has been convicted of murder in the second degree and sentenced to solitary confinement for twenty years.

Joint Meeting of Two State Societies.—The Illinois State Medical Association will meet in East St. Louis, on May 18–20, 1897, and the Missouri State Medical Association will meet in St. Louis on the same days. It is proposed to hold a joint session of the two societies on one of these days, and this to be followed by an excursion in common on the Mississippi River.

The New York Doctor's Successful Rivals.—Here, then, in this one corner of the city, stand side by side a luxurious hospital with a very large out-patient department; a great building for the free treatment of the rich poor who can pay for their rooms; a clinic only to be described as palatial in its appointments, and to which patients ride in their carriages; and a large lying-in establishment, whose advantages have been widely advertised. Is it any wonder that the local practitioner starves? All that is needed to reduce the mass of the profession to pauperism are two or three more such institutions, endowed with a million or so apiece by sham philanthropists.—*The Clinical Recorder.*

For the Benefit of Young Male Consumptives.—A woman, who recently died in Paris, Mme. Géroult by name, has bequeathed her entire fortune to the Assistance Publique of that city, to be devoted to the establishment of a hospital for young men from fifteen to thirty years of age, suffering from pulmonary tuberculosis.

Sir Spencer Wells was an ardent advocate of cremation, and left directions that such disposition should be made of his own body. Ten years ago, when discussion on this mode of disposing of the dead was active and somewhat acrimonious in England, he wrote a letter to the *Times*, advocating cremation, not only from a sanitary point of view, but pointing out what an impetus its adoption would give to the arts. Cinerary urns, he contended, have in all countries where the practice is carried out been among the most beautiful features of the temples and other resting-places of the departed.

The Pasteur Gardens.—The municipality of Mexico has given the name of Pasteur to the gardens situated in front of the National School of Medicine in that city.

Sanitary Plumbing in San Francisco.—It has been discovered that the plumbers employed in the San Francisco City Hospital failed to connect the pipes with the sewers, and that all the waterclosets, etc., have been discharging their contents on the ground under the hospital wards. But bad as the atmosphere of the wards is, says the *Pacific Medical Journal*, the board of health finds the place permeated with a moral corruption, even worse than the atmospheric pollution. The board, our contemporary continues, is completely under the domination of the politicians and is forced to fill all the places in the department with creatures of the party leaders.

The American Medical Association in Denver.—Colorado, especially Denver physicians, are discussing rather nervously the expediency of inviting the American Medical Association to meet in Denver in 1898. They would like to have the advertisement which the meeting would give the city and State, but they question whether it would be worth the expense. It seems to be taken for granted that the American Medical Association would go to Denver if invited.

Jefferson Medical College.—Dr. J. Chalmers Da Costa has been elected clinical professor of surgery in Jefferson Medical College. He had been for a number of years demonstrator of surgery and chief clinical assistant in the out-patient surgical department of Jefferson Hospital. In the former position he will be succeeded by Dr. George W. Spencer, in the latter by Dr. Martin H. Williams.

The British Medical Association.—Dr. William Osler, of Baltimore, will deliver the address on medicine before the British Medical Association at the Montreal meeting in August next. Dr. Stephen Mackenzie will be chairman of the section on medicine, Mr. Christopher Heath of the section on surgery, and Mr. Watson Cheyne of the section on pathology. Lord Lister has announced his intention to be present.

Homœopathic Surgeons.—The *Hahnemannian Advocate* bewails the fact, which it thinks is humiliating to the members of that school of medicine, that "the brightest, keenest, wisest men to be found standing under the banner of *similia* are surgeons," and that "our brightest students so quickly cast to one side the cherished principles and precepts of the master and eagerly grasp the opportunities for securing manual dexterity." The reason for this is, it says, that homœopathy is not well taught in the schools.

Philadelphia Neurological Society.—A stated meeting of the Philadelphia Neurological Society was held on February 22d, the president, Dr. C. W. Burr, in the chair. Dr. Alfred Stengel exhibited a case of arsenical neuritis in a child treated for chorea with Fowler's solution. Dr. F. X. Dercum reported a case of primary neurotic atrophy and one of disseminated sclerosis of hemiplegic type, and exhibited also three cases of cerebral spastic palsy in one family. Dr. D. Riesman exhibited two cases of brachial tremor, one probably as a manifestation of paralysis agitans and the other of hysteria. Dr. W. G. Spiller exhibited a case of right hemiplegia with aphasia, setting in after emotional disturbance. There was a difference of opinion as to whether the case was one of hysterical or hemorrhagic origin. Dr. H. A. Hare reported a case of hemiplegia exhibiting extensive brachial œdema.

The Prince of Wales' Fund.—In the appeal for subscriptions to this fund, the Prince of Wales says that, the Queen having no wish to express a preference for any one of the many proposals suggested for commemorating the sixtieth year of her reign, he feels at liberty to bring to the notice of the inhabitants of London a project which lies very near his heart, "its object being to attach the sentiment of gratitude for the blessings which the country has enjoyed for the last sixty years to a scheme of permanent beneficence." He proposes therefore to invite subscriptions of one shilling per annum and upward from all classes for "the Prince of Wales' Hospital Fund for London, to commemorate the sixtieth anniversary of the Queen's reign." The amount which it is hoped to raise each year is from £100,000 to £150,000. It is proposed to seek subscriptions not only from individuals but also from railway and other corporations, owners of land, and all other large employers of labor.

Baron Lister of Lyme Regis in the County of Dorset is the official title of the new medical peer.

Disinfection of Mails from Plague Districts.—The Pennsylvania State board suggests to the postmaster-general, in view of the fact that the plague is a germ disease, the importance of taking the necessary steps to insure the disinfection of all mails coming from districts in which the disease may prevail.

An Accident Ward at the Charité.—What *The Hospital* calls "rather a novel departure" has been taken at the Charité Hospital, Berlin. This is the establishment of a department for accidents only, where the patients will be retained until their complete restoration to health. Medical baths and apparatus will be provided to further recovery. The patients will be expected to pay three marks per diem. Members of trade unions will be allowed to receive the visit of the doctor of their association in conjunction with the visiting staff, who will thus be able to watch the treatment and progress of cases sent in by them.

Physicians and Druggists.—A Prussian law forbids physicians to direct their patients to any special pharmacist in order to have their prescriptions compounded. A medical man has recently been fined three hundred marks, under this statute, for displaying in his waiting-room a notice requesting his patients to have their prescriptions dispensed by a neighboring druggist. In the course of the trial another law was cited which debars pharmacists from giving Christmas presents to physicians.

Pathological Society of Philadelphia.—A stated meeting of the Pathological Society of Philadelphia was held on February 25th, Dr. W. C. Burr in the chair. Dr. S. M. Hamill exhibited a parasitic cyst of the spleen, probably either ecchinococcus or pentasto-

ma. Dr. M. H. Fussell exhibited a ruptured aneurism of the abdominal aorta and also one of the thoracic aorta; further, a specimen of purulent cerebro-spinal meningitis from a man who had presented during life only general malaise and irregular elevation of temperature. Dr. J. D. Steele exhibited a specimen of syphilis of the liver, with microscopic sections, and also sections of syphilis of the femur. Dr. D. Riesman exhibited hemorrhagic infarction of the lung from a case of empyema in an infant, with sections showing micro-organisms in the thrombus. Dr. W. M. L. Coplin exhibited a specimen of purulent cystitis from a case of fatal gunshot wound of the spinal cord in the dorsal region. Dr. D. Riesman exhibited specimens of small round-cell sarcoma of both kidneys from a cat. Dr. Joseph Sailer exhibited a section displaying degeneration of the ganglion cells of the crus cerebri.

Philadelphia School of Anatomy. — The annual commencement of the Philadelphia School of Anatomy was held on February 24th, diplomas being awarded to one hundred and fifty-two graduates.

College of Physicians of Philadelphia. — At a stated meeting of the section on general medicine of the College of Physicians of Philadelphia, held on February 23d, Dr. D. L. Edsall read a paper on "The Examination for Clinical Purposes of Hydrochloric Acid in Gastric Contents;" and Dr. H. A. Hare, a paper on the "Relative Value of Digitalis in the Heart Disease of Childhood."

Insomnia is reported to be unusually prevalent in London this winter, the cause, as alleged by some advocates of "seasonable weather," being the mildness of the winter.

The French Army Medical Service.—There is much dissatisfaction among French army surgeons over a new rule, making promotion depend not upon seniority, but upon "merit," which those passed over read "favor." The resignations are increasing in number constantly, and a large number of the surgeons resign as soon as they have completed thirty years' service, which entitles them to a pension.

Vital Statistics of Philadelphia.—For the week ending February 20th there occurred in the city of Philadelphia 530 deaths—10 less than during the preceding week and 59 more than during the corresponding week of the previous year. There were 150 deaths in children under five years of age. The most important individual causes of death were pneumonia, 115; pulmonary tuberculosis, 57; heart disease, 52; diphtheria, 27; old age, 21; convulsions, 20; influenza, 18; apoplexy, 17; carcinoma, 17; bronchitis, 14; nephritis, 12. There were reported during the week 85 cases of diphtheria, 62 of scarlet fever, and 26 of typhoid fever.

Medical Fishermen.—The *British Medical Journal* notes a recent article in which François Coppée calls the attention of the public in France to a strange arrangement in the French fishing-fleets. By the law of their country French shipwrights and sea captains are bound to see that every kind of craft that sails with a crew of over twenty men carries a medical officer. Very large smacks put to sea for Iceland and Newfoundland in considerable fleets every season. The shipwright or owner, obliged to conform to the law, but unwilling to pay for a useless pair of arms, demands that each doctor should help the fishermen to cut up and salt the fish. M. Coppée states that at Granville, Paimpol, and Fécamp as many doctors as are wanted can be found only too ready to accept these terms. The duties of the surgeon on British whaling-vessels of half a century ago were very similar. Dr. F. E. Barnes, in a recent letter to *The Lancet*, describes his experience in the *Cowslip*, which was perhaps the last sperm whaler out of England in 1856–59. The surgeon on such a ship had a rough time of it, having to go aloft daily regularly on the lookout, and being held responsible for the safety of the boats when away from the ship after whales, not a nice job in squally weather or when the boats were away after sundown and the lights of glimmering lanterns had to be kept sight of, with only four boys to work the ship. He had also to take an occasional spell at boiling oil.

Professor Nocard, of Alfort, has received the award of the Lacaze prize, $2,000 in value, for his researches in animal tuberculosis.

Dr. James E. Pilcher, captain and surgeon U. S. A., now at Columbus Barracks, has, we learn from the *Columbus Medical Journal*, been appointed on the editorial staff of the *Journal of the American Medical Association*.

Philadelphia County Medical Society.—A stated meeting of the Philadelphia County Medical Society was held on February 24th, the president, Dr. James Tyson, in the chair. Dr. W. W. Keen read a paper entitled "Resection of the Sternum for Tumors, with a Table of the Previously Reported Cases," in which he detailed the history of two cases wherein he had performed this operation, exhibiting also one of them. Dr. F. X. Dercum read a paper entitled "A Brief Outline of the Theory of the Neuron as Applied to Normal and Pathologic Mental and Nervous Processes." Dr. G. Hudson Makuen exhibited a boy, fifteen years old, who, though otherwise intelligent, had, as a result of illness and related conditions, never learned to speak intelligibly. Four weeks of training in the clinic for speech defects of the Polyclinic Hospital had resulted in the acquirement of a considerable degree of facility in speech, which it was hoped in a short time to increase sufficiently to enable the boy to speak almost as well as any one.

New York University Alumni.—The alumni of the medical department of the New York University met for their twenty-sixth annual dinner at the Hotel Waldorf, on February 23d. There were about one hundred members of the alumni present. Before the banquet the thirty-first annual business meeting of the Alumni Association was held, and there was an election of officers. Dr. H. F. Williams, '73, was elected *President* to succeed Dr. Charles E. Quimby, '78.

Society Reports.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, January 8, 1897.

ANDREW H. SMITH, M.D., PRESIDENT, IN THE CHAIR.

Report of a Case of Suppurative Appendicitis Complicating Seventh Month of Pregnancy; Operation; Recovery.—DR. ROBERT ABBE reported the case. "Mrs. S——, primipara, pregnant seven months, was seen with Drs. Draper and Heath, July 8, 1896. For five days she had been suffering with severe symptoms of appendicitis. When I saw her her temperature was 103.5° F.; pulse, 120. She lay upon her side in order to breathe, her distention by pregnancy as well as tympanites necessitating it. She was vomiting and presented the characteristic appearance of grave peritonitis. In spite of the unpromising outlook I operated three hours later. The relation of the viscera in the abdomen was of interest. A rather long lateral incision showed the round and broad ligaments drawn up into the usual site of the caput coli, which was crowded up into the lumbar region, the lateral abdomen and pelvis being filled by the uterus. The appendix was squeezed between the uterus and iliac fossa, where, when it was distended enough, it had burst, and set up septic peritonitis over the right half of the uterus, involving also the broad ligament, a portion of the rectum seen in the pelvis, and some coils of small intestine which came into view. There was a generally foul septic look about all the parts coming into view, and three or four ounces of soupy turbid effusion came from the precincts of the trouble. There were no lymph barriers apparent anywhere, though shreddy lymph was sponged away with the cleansing. It was impossible to irrigate; excepting to thrust sponges wet with salt solution among the invaded parts and mop them dry. The appendix, which had swollen and burst at the end, was cut off and its stump inverted by suture. Iodoform gauze was packed generally about that half of the abdomen and the wound left open. The temperature was normal on the second day and convalescence was rapid. The fœtal heart was vigorous at 140 and fœtal movements continued active. A vigorous boy was born two months later without complication. Mother and child remain well."

DR. CLEMENT CLEVELAND said he had never met with a case of the kind reported by Dr. Abbe. Some years ago he had opened the abdomen for pyosalpinx and found a suppurating appendix vermiformis attached to the left tube and ovary. All were removed. It was only under such circumstances that he operated for appendicitis.

DR. R. F. WEIR expressed special interest in the question raised by Dr. Abbe as to the extent of the peritonitis. He must confess that his views were somewhat at variance with those of the majority of surgeons with regard to general suppurative peritonitis. He had never himself been able to save a patient, nor had he seen one saved. By general suppurative peritonitis due to appendicitis he referred to that form in which the pus was general over the whole peritoneal cavity. He did not mean adhesive inflammation. While he hoped Dr. Abbe had had a case of recovery from general suppurative peritonitis, yet he was not sure that his case had been described as belonging to this class in the fullest sense. Usually the patients who recovered, and whose surgeons believed they had saved them by operation, did not belong among the worst class. They were usually cases either of fibrinous peritonitis or of suppurative peritonitis which did not involve the whole peritoneal cavity. Here was a point of interest to all, that there could be so large an extent of peritoneal surface involved and yet the peritonitis be limited. He had several times seen more than half of the abdominal cavity apparently in a state of intense suppurative peritonitis while the remaining portion was comparatively free. He had been fortunate enough in two or three instances to save such patients. Having thus explained what he meant when he had expressed regret at not being able to report a case of recovery from general suppurative peritonitis, he would ask Dr. Abbe whether his case belonged to that kind or whether it was one of fibrinous peritonitis.

DR. WILLIAM T. BULL was able to recall one instance of a patient three or four months pregnant, who was admitted to the New York Hospital with appendicitis and was submitted to operation very promptly. The condition found was that of appendicitis and local suppurative peritonitis; the termination was favorable. False membrane had not, he thought, extended to the uterus, which was felt but not seen. As somewhat in line with this class of cases, he recalled one of large uterine fibroid, the tumor reaching half way up to the umbilicus, in a woman over sixty years of age, to which he and Dr. Coe were called in consultation by Dr. Mendelson, on account of what was found to be suppurative appendicitis. Operation about seven days after the commencement of the attack. The whole inflammatory process had gone on independently of the uterine tumor. As bearing upon the question of the influence of operations in the pelvis on the course of pregnancy, Dr. Bull mentioned a case of fibroid which sprang from one horn of the uterus, which was noticed about the second month of pregnancy and which was operated upon in the fourth month. The fibroid was about the size of two fists, the pedicle about as thick as three fingers. This was some years ago and the pedicle, including its insertion at the uterus, was fastened into the abdominal wall and separated by slough at the end of three weeks. Notwithstanding the fact that the operative attack so closely approached the uterine cavity, pregnancy went on and terminated satisfactorily.

DR. ABBE replied to the question raised by Dr. Weir, which he thought was among the most important ones in the whole domain of surgery. He did not see how it could be stated that the infection was limited when no limiting barrier was found. In his case all the loops of intestine which appeared in the wound were infected to a moderate extent. While the distant ones were least infected, still none was free. He thought that if the peritonitis had been allowed to continue, it would have been more purulent the following day, still more purulent the next day, and therefore could be called purulent peritonitis even though the pus were not of the yellow variety. He could not see how one could assume that the entire peritoneal cavity was not involved when no limiting barriers were found and all of the coils of intestine seen were involved. During the operation most of the pus was removed, and that which was left at a distance in the cases of recovery nature was able to take care of. It seemed to him very reasonable that nature should care for a small amount of peritoneal infection, assuming that the principal part had been removed, provision made for drainage, and that the bowel was acting healthfully. Indeed, it seemed to him that in every case of recovery from purulent peritonitis we must look for some such explanation. When about two years ago Dr. McBurney read a paper on this subject and reported some cases, Dr. Abbe looked over all of his cases of purulent peritonitis and found that about seven out of thirty had ended in recovery. They were, he thought, of the gravest type, and in some all of the coils of the small intestine which came into view were

smeared and infected. Still the patients recovered, and in one the sequel showed that there must have been more general infection than that which came into view, for obstruction took place and secondary operation showed that a coil of intestine on the opposite side had been bound down by an adhesive band originating, no doubt, with the attack of peritonitis a few weeks before.

External Œsophagotomy for Removal of a Tooth Plate from the Œsophagus.—Dr. William T. Bull read the paper (see page 330).

Dr. Abbe said he had occasion twice to take dental plates out of the œsophagus, once at the end of twelve days, and again after several months. In the second case it was not known that the man had swallowed a plate, for it had happened during a state of intoxication on a Thanksgiving evening. Stricture of the œsophagus developed for which he sought counsel. The ordinary œsophageal bougie did not reveal the presence of a plate, but it did detect stricture. The plate obstructed its passage, but that was all, and it was only by accident that Dr. Abbe's suspicions were aroused and he was led to try a steel bougie à boule, which showed that the plate containing a tooth was present. In one case Dr. Abbe performed external œsophagotomy, in the other the foreign body was extracted with forceps.

Dr. Weir had once removed a jackstone from the œsophagus by external œsophagotomy, and the patient recovered. In another instance, in which a man had swallowed something and several unsuccessful attempts had been made by others to remove it, he performed œsophagotomy for the inflammatory process which had developed in the neck. The foreign body was not found, but the patient recovered.

Dr. Weir thought the skiagraph shown by Dr. Bull did not represent the dental plate in the œsophagus very plainly, and he should dislike to base an operation upon it alone.

Dr. Bull replied that the skiagraphic plate was a very large one, was not perfectly developed, and the photographer admitted that it was rather poorly printed. Still, with the history of the case before one, such a plate would be of great service.

The president, Dr. A. H. Smith, mentioned a humorous case. A man on retiring brushed a plate carrying one tooth, missed it, supposed he had swallowed it, and Dr. Smith was sent for in the night to extract it. He passed a number of instruments down the œsophagus, but met with no obstruction, and came to the conclusion that the plate had entered the stomach. As the plate had a projection on both sides for attachment to its neighbors, it was a question what might become of it in the stomach. The patient was fed for about three weeks on bran bread, etc., and the stools were watched closely, but the plate was not found. After three weeks, when the man had about recovered his equanimity, the servant, while sweeping the room, found the plate under the washstand.

The Treatment of Depressed Fracture of the Malar Bone.—Dr. R. F. Weir read the paper (see page 335).

Dr. Abbe said he had had his first experience with depressed fracture of the malar bone two months ago, and was not aware that Dr. Weir had had similar experience. His case was that of a young man whose head had come in collision with that of another man while they were playing football. Dr. Abbe saw him on the third day. His face was greatly disfigured. The malar bone was broken in, and when raised with a probe introduced under the lip it would not remain in place, but would dance back and forth in the antrum. He then supported it with a drill passed through the solid part of the zygoma, and after ten days or two weeks it had healed solidly in place and the drill was removed. There was no scar except a dent in the skin. The mouth wound was closed at once. He thought the advantage of this method over that of packing the antrum might in some cases be great. The procedure was very simple and preserved the antrum from possible infection. The only disadvantage was the small puncture scar made by the drill. Mastication was not interfered with. Dr. Abbe added that the lower wall of the orbit was also depressed by the injury and the appearance was very uncanny.

The President had once seen a case of depression of the malar bone and lower orbit caused by a railroad accident. Dr. Sands also saw the patient. Nothing was done, and there was horrible deformity the rest of life. Such an operation as had been described to-night would have been of inestimable value to that woman.

Case of Malarial Hæmaturia, with Some Peculiar Features.—Dr. Andrew H. Smith read the history of the case.

Dr. W. Gilman Thompson had seen four cases of mixed typhoid and malarial infection; but only in the one reported by the president, which had also come under his observation at the Presbyterian Hospital, had there been hæmaturia. Certainly hæmaturia in malarial affections was rare in this part of the country. Besides finding the plasmodium to confirm the diagnosis of mixed infection, there had been the typical symptoms of typhoid, such as the eruption on the abdomen and in some hemorrhage from the bowel. The temperature had run a very irregular course, falling in the interval of the malarial paroxysms.

Dr. A. Alexander Smith said that within three years he had seen a case of malarial hæmaturia in the person of a recent graduate in medicine who had no suspicion of the cause of his hæmaturia. Since the blood in the urine seemed to make its appearance periodically, he interrogated the patient closely and learned that he had come originally from the South where malaria was prevalent. His hæmaturia was of that kind which was often described as of mild character, not continuous, and most abundant just after the malarial paroxysm, which was of the third-day variety. During the intervening day the eye could detect no discoloration of the urine by blood. The case yielded to antimalarial treatment.

The speaker said he had recently received a letter from a doctor in a town in North Carolina, asking if malarial hæmaturia was frequent in the vicinity of New York, and added that in his section it was very frequent, occurring in from fifteen to eighteen per cent. of all cases of malaria. This seemed to Dr. Smith a somewhat extraordinary statement. Several of the members of the society said they had received a letter to the same effect, presumably from the same doctor.

The President had recently read in periodicals that some physicians in the South and West believed that hæmaturia occurred in malaria only when quinine was used. They were inclined to attribute it to the quinine rather than to the malaria. The fact that in the case of mixed infection of typhoid and malaria the temperature in the interval of the malarial attacks went down as if typhoid fever were not present had impressed him as very interesting.

Dr. H. M. Biggs asked whether mixed infection of typhoid and malaria was more common this year than previously. He had scarcely ever seen a case before, but this year three or four cases had come under his observation.

Dr. Thompson remarked that malaria had been more common in the vicinity of New York this autumn than for some years before, while typhoid had been of about the usual frequency. Doctors were more on the lookout for the mixed infection now than

formerly. The first case which he had seen and reported occurred four years ago. In the past it had been suspected that malaria and typhoid might occur at the same time, but it was not proven. Now the clinical diagnosis was confirmed by blood examination. Regarding the fall in the temperature, in one or two of his cases it had been so pronounced that he had suspected hemorrhage from the typhoid ulcers, but there was no subsequent evidence, and all of his cases of mixed infection had terminated in recovery. Quite a number of cases of mixed infection had been reported lately from different parts of this country and abroad.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Stated Meeting, February 16, 1897.

L. F. BISHOP, M.D., CHAIRMAN.

The Scientific Spirit in Practical Medicine.—DR. BISHOP chose this subject for a brief inaugural address. He said: "In assuming the chair of the medical section of the New York Academy of Medicine, I can but feel the grave responsibilities which inhere to this position. In this section all the currents and undercurrent of our science should meet, to form a strong tide toward truth and unity in medicine. It is the duty of this section to uphold the dignity of general medicine in its relation to the other sciences and to the needs of humanity. The specialist has to do more frequently with local diseases, which, important though they may be to the individual at the time, still as a rule are mere incidents in his life. In conditions which permanently affect health and happiness, which lengthen or shorten life, and which threaten death, it is the general practitioner whose advice, counsel, and support are sought.

"We must, in the first place, invoke the true scientific spirit to control our deliberations and direct our work. The scientific spirit places the love of truth above prejudice, expediency, or even immediate concrete application. It approaches all subjects with an open mind, willing to receive light from any source and whatsoever be the medium through which it comes. It denies nothing, however improbable, until it has been disproved; it accepts nothing, however plausible, until it has been verified by the experimental method. The scientific spirit, while it seeks enthusiastically new truth and rejoices in fresh fields, finds its truest expression in that love of exact knowledge which labors patiently and intelligently for the perfecting of established truth and the correction of error. Thus, while from time to time we may have presented to us new products of discovery, yet if we meet here to perfect, chasten, and simplify our knowledge of the fundamental art and practice of medicine, we shall accomplish what, to my mind, is the chief value of the work of this section, both to ourselves and to the profession at large.

"Truth, however old, is always attractive. I remember, when the beauties of chemistry were first revealed to me, spending hour after hour repeating over and over again simple chemical reactions. There was nothing new to learn and nothing new to see in the immediate precipitations or the play of colors. The enjoyment consisted in the fact that after earlier years of harassing study in the schoolroom, there had dawned at last the image of something fixed and definite in human knowledge, the recognition of a sphere in which the appeal was to truth alone, and not to human authority or tradition.

"We must not be discouraged with the constant repetition of medical and scientific truth. If we have the true scientific spirit, the repetition will give us pleasure, will give us a sense of stability, will strengthen our love of truth, and relieve us from the pathological craving for novelty. We should seek always that which is true rather than that which is novel. But we should equally be ready to give a fair, impartial, and unbiassed hearing to any one who has something which he believes contains the germ of truth. Many a man is saved from the propagation of a false theory, or the carrying on of a false system of practice, or even the founding of a new sect in medicine, by kindly criticism and correction; such kindly reception and criticism should certainly be granted to those who bring the results of honest thought and faithful investigation before a body of men actuated by the scientific spirit. Every living error has in it a germ of truth, that gives it vitality and allows it to live. If by dogmatic assertion or violent criticism we attempt to destroy this error, the germ of truth may become forever inseparably adherent to falsehood; but take the new theory into the scientific assembly, allow it full expression and opportunity to vindicate itself, and by and by the gentle handling of mature and judicious minds will separate the little germ of truth, to add it to the sum of human knowledge, and the mass or error will fade so quietly away that its previous presence is almost instantly forgotten.

"We, therefore, appeal to you to bring to this section the results of your work, however incomplete or unfruitful they may seem, and we pledge you a fair hearing, kindly criticism, and, we trust, helpful suggestion."

Stimulation in Acute Diseases.—DR. HORATIO C. WOOD, of Philadelphia, opened the verbal discussion of this subject. In entering upon any discussion, the first thing necessary seemed to be a definition of terms. Some years ago he would not have hesitated to say that he knew what stimulation meant, but he must confess that if asked to-day to define the word he would have considerable misgiving. He had lived to see one great revolution in the science of therapeutics, and it seemed to him that we were almost in the presence of another, and that the therapeutics of the next decade would be very different from the therapeutics of to-day. He thought the work of Gaskill, of London, had not received the attention which it deserved. It went to show that there were two periods in the life of the heart—a period of action, of functional performance; and then a period of rest. The period of rest, of upbuilding of structure, was dominated by trophic nerves: the period of functional excitement, of tearing down of structure, was dominated by nerves antagonistic to the inhibitory. Dr. Wood believed this was the plan of the whole animal—function performed at the expense of structure: then rest, reconstruction, the two processes governed by antagonistic nerves. When we thought of this in connection with the subject of stimulation, the difficulty of the situation at once became apparent. Should we call that drug a stimulant, if there was such, which produced quiet, rest, upbuilding of structure? Or should we call the drug a stimulant, if there was such, which promoted functional activity and destruction of tissue?

Setting these questions aside for a moment, there was another class of drugs which, so far as we knew, neither promoted rest and upbuilding of structure nor functional activity with destruction of tissue, but which in some way appealed to the vital power of the structure and enabled it to resist morbific influences. We did not know whether they acted chemically, as stimulants, or in what manner, further than that they added in some way to the resisting power of the tissues to invading micro-organisms.

Passing, then, to drugs themselves, there were some, like aconite, which only depressed function. We

called them sedatives. Then there were certain drugs which, like strychnine or digitalis, excited functional activity and caused death in a moment of functional activity. On the other hand, there were certain substances, such as alcohol, ether, ammonia, which whipped the heart into furious activity at first and then produced paralysis, so that death took place in relaxation. Were all these substances stimulants?

When we looked at the process of disease which we wanted to reach by stimulants, we noticed that there was so-called exhaustion. Exhaustion was lack of force, lack of power. And there was depression, which was not lack of power, but lack of functional activity for the moment. In passing, Dr. Wood said a word with regard to that form of exhaustion called neurasthenia. We thought we knew a great deal about it nowadays, because we called it neurasthenia. But did we ever think of the fact that names were, after all, but toys, with which men amused themselves as a child might amuse itself with a doll, and thought it knew the thing because it knew the name? In olden times they called neurasthenia debility, and later nervous debility.

Returning to the subject of exhaustion and depression, what we wanted to do, perhaps, in the future, was to get some drug which would build up structure. The loss of resistive power was neither exhaustion nor depression. In diphtheria it was not the exhaustion of the throat nor its depression which deprived it of the power of resisting the micro-organisms. When we came to treat individuals we had to think of all these things, but, unfortunately, we did not know our drugs to-day so as to be able to apply these principles as well as we ought. Was it not astonishing that millions of dollars in these United States were donated to art galleries and all sorts of things of comparatively little use, when there was not a dollar to be found to pay a few men of genius, that they might devote their lives to finding out the issues of life and death? A million, or even half a million of dollars properly directed would in the next ten years revolutionize medicine. But it did not come.

To apply these principles, take a simple case of pneumonia. What was to be done in a case of pneumonia? In his opinion, one had first to learn this great therapeutic principle, namely, that although the pathologist labelled the disease with a certain name, to the therapeutist it was not the same disease. To the therapeutist pneumonia was no more pneumonia than it was cholera, or yellow fever, or anything else in different cases. What was life to one patient was death to another. The first principle, then, was to study the individual for that particular time. What was to be done in the case of a feeble man when stricken down with pneumonia? Hold him up, sustain him. But a strong, robust person, in the vigor of manhood, developed pneumonia while facing a Dakota blizzard; his heart was rapid, his pulse bounding, his temperature high. Have we to hold that man up? No. But by bleeding him we might save life; or the same thing could be accomplished—giving rest to the lungs and the heart—by administering veratrum viride. This did not cure the pneumonia, it did not put an end to the coccus; but the coccus in pneumonia was only one of the factors. We stayed the local ravages and gave the man a chance to recover his power. But there came a time when the heart was wearied by the appeals made to it from everywhere, and the forces were being reduced. To give a sedative to that man's heart would do harm. We would give him a substance like digitalis, which, if there were any power left, would give the heart force to drive the blood through the lungs by the energy of its systole. But it should be noted that digitalis did more than this, for it was the one substance which was known to have the power to which he had referred, of giving nutrition to the tissues. It was a stimulant not merely to functional activity, but also to nutrition. The pneumogastric was undoubtedly the trophic nerve of the heart, and this drug stimulated the trophic heart nerve. It brought long periods of rest for upbuilding, and it brought a strong systole. It was this power of increasing the trophic activity of the heart which made digitalis so valuable in the long stages of a failing heart. It gave energy to the contraction, and filled the heart with blood at a time when before that energetic contraction little blood had got back through the coronary arteries to the exhausted, starving muscle.

He had no faith in the modern chemistry of digitalis, nor in the ancient either. It probably acted through different substances, for it was almost inconceivable that one substance or chemical principle should act on two functions apparently so antagonistic.

Take a case of acute collapse, of surgical shock. What was surgical shock? Vasomotor paralysis chiefly. A stimulant was wanted exactly adapted to the case. When he was a student, a man was brought into the hospital, suffering from shock. They poured alcohol into him, and he wrote in his diary that alcohol to bring about recovery from surgical shock was about as useful as alcohol poured down a rat hole. Why? Because, if alcohol had any effect on the vasomotor nervous system, it was depressing. More than this, the heart itself passed into depression the moment one gave alcohol in excess. The stimulant must be adapted to the needs of the individual case at the time. Alcohol was a mild stimulant to the heart, a very mild one. Go into the laboratory, and it would be found to raise the blood pressure a little, but not nearly so much as would cocaine, strychnine, digitalis, or a host of other drugs which were sometimes used in that other disease which he took as a second example, typhoid fever. He doubted very much whether the stimulating power of alcohol in typhoid fever counted for much. But had it not other functions? Probably it had the power of increasing the resisting forces of the tissues. But he could not prove it. Here was another subject which needed investigation. There was this curious thing about alcohol, which set it aside from all other drugs so far as his knowledge went, namely, that one might give a man in health half a pint of whiskey, and the odor would be noticed from the breath and everywhere; but give the same amount in typhoid fever, and it would not be noticed at all. As soon as a sufficient quantity was given in fever to be noticeable in the breath, it indicated that we were overdoing the stimulation. This was the best practical guide known to him for the use of alcohol in typhoid, for as soon as the odor appeared in the breath it meant that the system had lost the power to burn it in the quantity administered. It indicated but did not prove that in these low fevers the drug probably acted in part as a stimulant, in part by increasing the resisting power of the tissues, but more probably than in any other way it acted by burning up in the system and supporting the tissues which were being destroyed by the fever. While that was probable, yet it was a subject for research.

When should alcohol be given in typhoid? Some said in the beginning, others said late, and a few said not at all. Dr. Wood said that, when given, it should be given for a different purpose and in a different manner at the beginning from what it was late in the disease. In the first instance, it should be given in small amount, teaspoonful or two-teaspoonful doses, and with the food, to increase the activity of the stomach and upper intestine in the time of their weakness, and to furnish something to the needs of the system which could be burnt up. But when the time came

when the patient was sinking, and all the functions seemed about obliterated, and the fever ran high in spite of cold baths, then give alcohol in such doses as the system could burn. That was the measure of the dose—whether it was a teacupful, a quart, or a Great Eastern.

When did other stimulants come in? When they were specially indicated. Digitalis should be given when there was danger of the heart failing, but not before the time came. In administering digitalis, let it be for the effect, not for the dose. If five minims were sufficient, let that be the dose. If a drachm were required to produce the effect, give it. The same rule applied throughout therapeutics.

With regard to the reinforcement of one stimulant with another, Dr. Wood mentioned an experiment which he had made some years ago, giving a dog chloral and resuscitating him with strychnine. After carrying this to the farthest point, he gave cocaine and the respiration came back to nearly normal. A man while reduced by erysipelas developed pneumonia, and in spite of strychnine as a stimulant he thought he would die, and all the doctors who had seen him thought he surely could not live. After leaving the house it occurred to him to give cocaine, and he did so. That man, with erysipelas, pneumonia, and six doctors lived. Think of it!

Definition of Terms.—Dr. William H. Thomson said we were under obligations to Dr. Wood for bringing before us one of the most important subjects in the whole range of medicine, namely, that of arriving at greater discrimination in our ideas of the sense of terms which we used in therapeutics. He had no doubt that the discussion would bring out a great variety of views with regard to stimulation and sedation or depression. Dr. Thomson gave us an example of pure stimulation—dry heat; as an example of pure sedation—moist heat, water at the temperature of the surface of the body. Cold first acted as a depressant, causing shock; but in the reaction which followed it was a powerful stimulant. There was no general nervous stimulant, and no general nervous sedative except death. Stimulants and sedatives acted only on a part of the system. Ammonia was a stimulant whose stimulating effect was neither preceded nor followed by depression; hydrocyanic acid was only depressant; opium was both a stimulant and a depressant at the same time. Dr. Thomson thought alcohol was a cardiac stimulant, but this effect was not so apparent in the pulse, because it at the same time dilated the arterial system. But it was sedative to the sensory nervous system, and the motor inco-ordination was due to that fact and not to paralysis of the motor centres. Of all words which needed defining or abolishing because they could not be defined, was the word tonic. Strychnine, iron, digitalis, sea air, mountain air, etc., were tonics according to the circumstances; yet how various and even incompatible in action!

Stimulation and Depression Not the Only Modes of Action.—Dr. Andrew H. Smith thought we became confused at the outset of the discussion by the idea that a change, if any were produced, must be up or down, stimulation or depression. This was no more necessary than that all motion must be up or down. The moment that we regarded any drug as simply increasing or simply diminishing function, we limited its action in an unwarranted way. There were variations in other planes as well as in the vertical. Alcohol, for example, acted in many directions. It influenced the heart, the arteries, the nervous system, it acted as a food, it restrained molecular movement and destruction. Regarding digitalis, it gave the heart more power, but it also, through action on the arteries, increased its work. Given, however, in larger doses, it seemed that the last-named effect counteracted the first to a less degree.

Dr. William H. Draper said he would limit his remarks to the two diseases which had been taken by way of illustration—pneumonia and typhoid fever. As to the necessity at times for stimulation in these two diseases, he thought there was no longer any question. He must confess that he was surprised when his friend, Dr. Wood, spoke of venesection as imperatively demanded in certain cases of pneumonia. In an experience of considerable length he had never seen such a case. He had also been surprised to hear the statement that alcohol used in shock might just as well be poured down a rat hole. He thought it was inconsistent with the rest of the speaker's remarks regarding that drug. Dr. Draper had long regarded alcohol as a stimulant and food. He had been pleased with the statement regarding the dosage of alcohol in typhoid fever, for he had himself been guided by the rule, essentially the same, contained in Graves and Stokes' "System of Medicine." What alcohol did in pneumonia and in typhoid fever was simply to stimulate the heart and keep up nutrition. As soon as the process in the intestine in the one disease and in the lung in the other ceased, then we should cease giving alcohol and give food instead. It should not be forgotten that pneumonia was not a disease which could be controlled by any drug.

Dr. Beverley Robinson thought none of us knew precisely what alcohol did. We did not know precisely what was the poison evolved in the various diseases which we counteracted with alcohol, but we did know that we frequently accomplished good results with its use. But it was a most difficult thing to decide how much to give and how often. It was necessary to be very careful in its use in alcoholic subjects. He was glad Dr. Wood had mentioned coca—not cocaine, but coca. Dr. Robinson had obtained effects from coca which he could not from strychnine or alcohol. He frequently used stimulants by the hypodermic method. Concentrated black coffee was often a very valuable stimulant in acute affections, like pneumonia, bronchitis, etc. Regarding alcoholics, effects differed at times according to whether whiskey, brandy, or some particular form were used, when chemical analysis might indicate no special difference. Rectal stimulation was mentioned, also applications over the heart, especially heat. Dr. W. Gilman Thompson had carried out experiments which proved that nitroglycerin applied directly to the heart was second only to heat as a cardiac stimulant.

Dr. R. W. Wilcox was in sympathy with Dr. Thomson's desire that the word tonic should be either abolished or more definitely defined, but attempts in that direction had been frequent and unsuccessful. But the word tonic did not cover any more heterogeneous points than did many others in medicine—stimulant, for instance. Regarding the statement made by one of the speakers, that alcohol in pneumonia did not diminish the duration of the disease—while it would be difficult to prove that it did, yet, since the same speaker admitted that it increased the resistance of the tissues, it would seem that it might limit the amount of the inflammation and the duration of the disease.

Dr. Joseph Collins said that the subject of stimulation in acute disease was by no means exhausted by a consideration of its application to the acute infectious diseases. Such diseases are self-limiting and tend toward recovery without medication, and in them stimulation means a temporary borrowing to assist nature. Stimulation is serviceable only in asthenic and asynergic diseases. Very few of the acute infectious diseases are thus characterized, except in the later part. All nervous diseases, whether acute or chronic, are of such a nature, and it is in the treatment of these

diseases that a knowledge of how intelligently to administer stimulants—and by that is meant substances that will increase the executive capacity of the nervous system in contributing to constructive metamorphosis—is of great service. Take two diseases of this category—acute melancholia and acute neurasthenia. Opium, to conserve the neural energies and prevent the exhausted nerve protoplasm from wearing itself out in futile efforts at repair, combined with rest and food, is the ideal treatment. Naturally, the objections to the administration of opium in asthenic nervous conditions were in mind; but, nevertheless, the only stimulants of any real service in these diseases are the alkaloidal ones. He had never been able to understand the claims of some that symptom medicines, stimulants, do not cure or assist in the cure of organic diseases, such, for instance, as melancholia. If a stimulant, whose action can be secured by one dose, conserves sufficient integrity of the organism and prevents it from undergoing dissolution until the constituents of the circulation restore it to a normal condition, the stimulant, the symptom medicine, has had an important part in the cure of that disease. Concerning the dose of a stimulant, it could not be stated in weights and measures, but in physiological terms the dose was the quantity that did the work and met the required indications or approached them, no matter how small or how large the quantity was.

Dr. Wood said, in closing, that his address was simply intended to be suggestive. He could not compass heaven and earth, and all that therein was contained, in twenty minutes. One speaker gave coffee and brandy, and found that the coffee acted as a stimulant. It reminded him of the man who half filled a tumbler with brandy and filled it up with hot water, and the hot water made him drunk. Another speaker had treated neurasthenia a year and attributed good results to morphine. Was not the man under hygienic care during that time? How did he know the drug did it? Regarding functional disease and functional remedy, Dr. Wood thought the time would come when these terms would be banished from our vocabulary. The changes had simply not been revealed by our microscopes. Regarding the word tonic, let us call that a tonic which built up structure. There we had the whole thing. The barbarism of new names had afflicted the profession enough. Regarding venesection, he had never seen a case of pneumonia in which he thought venesection was imperatively demanded, but he had met intelligent doctors who practised among a hardy, robust class of people, descendants of the men who deserted from the Hessians and who spent their lives out of doors; they had told him that if they did not bleed these people when they got a pneumonia they would die. We were too apt to be bound by the narrowness of our own experience, and infer that because the people among whom we practised—enfeebled by alcoholism, by syphilis, and the degenerating influences of luxurious living—did not require venesection when they contracted pneumonia, therefore venesection was never demanded. We were like the frog which thought its own mudhole was the limit of the world, until it climbed up the bank and saw many larger ones.

English as She is Translated from the German.—A translation from Dr. Hillebrecht's article on the treatment of scrofula and "tubercular," incorporated in a circular just issued by a drug house, begins: "Who has opportunity to witness many dissections will literally get used to it, to find, by dissections for other causes of deaths, by a large percentage, at least in half of the cases, as occasional and incidental observations, old, healed tubercular hearths."

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 22, 1897.

Robert A. Murray, M.D., Vice-President, in the Chair.

Pulmonary Tuberculosis and the Health Board.—The following was the report of the committee on hygiene referred to the *comitia minora* at the last meeting:

"Realizing the need of proper measures for preventing the spread of pulmonary tuberculosis, and regarding it an essential preliminary that all physicians be impressed with the importance of making an early diagnosis of the same by microscopical examination of the sputum, we earnestly recommend that physicians avail themselves of the offer of the bacteriological department of the board of health to make such examinations. We approve of the compulsory reporting of cases of pulmonary tuberculosis, if the inspectors are forbidden to visit or have any communication with the patient without the consent of the attending physician, believing that the attending physician is capable of giving all the necessary instructions.

(Signed) "W. H. Katzenbach, M.D,
"Robert C. Myles, M.D.,
"Charles N. Dowd, M.D.,
"Egbert Le Fevre, M.D."

Dr. Le Fevre moved that action on the resolutions be postponed until a future meeting, that more time might be given to discussion of the scientific subject of the evening. Carried.

The Diagnosis of Malaria.—Dr. William Osler, of Baltimore, read the paper. Points of interest in regard to malarial fever were: 1. It was a disease well known to the old Greek and Roman physicians, some of whom gave a wonderfully accurate description of its clinical varieties. 2. It remained after two hundred years the only acute infection for which we had an absolute specific. 3. It was the most important known disease due to a protozoon parasite. 4. Physicians were prone to diagnosticate malaria for other diseases, and other diseases for malaria, which led to serious errors in vital statistics.

There were three well-known varieties: 1. The tertian organism, which matured in forty-eight hours and produced quotidian paroxysms if two crops were present, tertian if only one. This was the parasite of common, simple, intermittent malarial fever of the spring and autumn. 2. The quartan parasite, which had a cycle of development of seventy-two hours, and if only one crop was present gave the regular quartan intermittent; if two or more crops were present, the paroxysms might occur every day or every other day. The quartan type was rare north of the Chesapeake Bay, Dr. Osler having found it in only about fifteen out of one thousand cases at his clinic. 3. The parasite of irregular malarial fever—the remittent, continuous, and pernicious types. This variety of organism was smaller, less readily recognized, was not so abundant in the peripheral circulation, and in pernicious forms might select curious sites, as the brain or mucosa of the intestines. It was further characterized by the development of crescents—a fact of greatest moment in diagnosis.

The recognition of the invariable association of these parasites with all forms of malarial fever, their etiological relation to the disease, and their importance in diagnosis, had resulted from the labors of Laveran and of his followers in Italy and other countries. The Italians deserved special credit for their continued work in this line. Much yet remained for investigators to do in showing the relations of the different varieties of these protozoons to one another,

the significance of the different forms, their life history outside of the body, and the mode of infection. Was it a facultative parasite? How long might it remain dormant in the system without producing symptoms?

It was not easy to obtain a correct knowledge of the forms of the malarial parasite. It required months of careful study and plenty of material. Some papers had been published in this country and in India, which bore evidence that the authors had approached the subject without due technical knowledge. Dr. Osler urged that in all doubtful cases, particularly in all cases of supposed mixed infection, as of typhoid and malaria, cover-slip specimens of the blood be preserved, which if necessary could be submitted to the judgment of an acknowledged expert. This specimen when stained was of almost equal value with the fresh blood.

The diagnosis of malaria in a large majority of cases was a very easy matter. The subject might be considered under three heads: 1, The diagnosis of regular malarial intermittent fevers; 2, of irregular, remittent, and pernicious forms; 3, of spurious malaria.

Simple intermittent, the only form of malaria common in this country, was characterized by paroxysms developed at the end of forty-eight hours if a single group of parasites was present, at the end of twenty-four hours if a double group existed or one which matured every day. There were three features by which the ague might be recognized: 1. The character of the febrile paroxysm. The duration of the pyrexia from the rise above 99° F. until the fall to normal was from eleven to twelve hours, rarely shorter, still more rarely longer. 2. The blood showed the hæmatozoa in all stages of development. There was no leucocytosis. 3. The administration of quinine caused rapid disappearance of the parasite and prevented further development of the paroxysms.

The three points referred to, but especially that of the period of fever, served usually to distinguish this type from the forms of septicæmia, since in the latter the period of fever varied, lasting from six hours up to eighteen or twenty. In septic conditions, too, there was absence of hæmatozoa, resistance to quinine, presence of leucocytosis. Dr. Osler had seen some cases of tuberculosis in the early stage, with chill and fever, treated for malaria and valuable time lost. Abscess of the liver was treated all over the country for malaria, and the patients were drenched with quinine. Cases of stone remaining in the gall ducts sometimes kept up an irregular fever for months or years, and were often mistaken for malaria. Influenza was sometimes diagnosticated malaria, as were various other affections. But the chief difficulty was in distinguishing between those cases of irregular malarial fever and remittent fevers simulating typhoid. Even in the hospital they had mistaken some cases of malaria for typhoid and given the patients the bath, rather to their displeasure. But the mistake consisted oftener in diagnosticating malaria as typhoid rather than typhoid as malaria. Important differential points were, first, the mode of onset, which in malarial remittent was much more sudden than in typhoid: absence of the protracted period of malaise, greater frequency of chills, rarity of epistaxis, more rapid rise of fever, rarely presenting a step-like rise, temperature reaching as high even as 106° F. by the second or third day, which was rare in typhoid. Perhaps the most important point in diagnosis between malaria and other fevers was the character of the fever in malaria which was intermittent from the outset.

A third point was the general appearance of the patient. In walking through the wards of a hospital one could pick out cases of malaria, particularly those of the intermittent type, by the facies within a week after the plasmodia had been nibbling at the red blood cells. There was anæmia, and, as a rule, it was shown by the sallowness of the complexion. During the first week there might be little difference in the appearance of the patient with typhoid and one with remittent malarial fever. Herpes, rare in typhoid, was exceedingly common in all forms of malaria. Such general features as bronchitis, gastro-intestinal disturbance, and headache offered no special criterion.

The fifth diagnostic element related to blood examination. Usually the diagnosis could be made clinically by the tenth day, and one might not find any evidence of malaria in the blood before the end of a week, while Vidal's reaction in typhoid was rarely elicited before the sixth or seventh day. Marked remissions of temperature, with falls to subnormal, and the development of anæmia, usually confirmed the diagnosis of malaria by the eighth or tenth day. If there were doubt, quinine would clear it up. The author believed they had not had a single case at the Johns Hopkins in which malarial remittent fever had resisted the proper administration of quinine for more than three days. But the parasites did not disappear so rapidly as in simple intermittent, for they were hidden in the spleen, in the bone marrow, and were more difficult to get at. The crescent form laughed at quinine, and would persist in the blood for weeks.

How far in paludal regions did typhoid fever take on malarial aspects? There was a rooted belief among physicians in various sections of the country that typhoid often presented malarial features. Failure to recognize the protean character of typhoid was the basis for this delusion. Dr. Osler had seen typhoid fever when he practised in Montreal, also in Philadelphia, and over five hundred cases had been treated in his wards at the Johns Hopkins, most of the latter coming from the same districts as those which furnished their cases of malaria; yet in these different cities typhoid had presented the same characteristics, and did not take on malarial features. Very seldom was there combined infection with the hæmatozoa and the Eberth bacilli. Combined with hæmaturia, Dr. W. Gilman Thomson's was the only case in this country. But the combination of malaria with pneumonia and with dysentery was not uncommon. Quinine would stop the malaria and the pneumonia would run its usual course. In some cases of typhoid fever a sort of septic fever developed after six or seven weeks, which might cause some suspicion of malaria, but certainly the majority of the cases was not malarial.

They had had two cases of pernicious malarial fever admitted to their wards which passed unrecognized, and Dr. Welch had made the diagnosis at autopsy. One was a case of suspected pneumonia.

What was spurious malaria? He did not know. One form of it was very fatal. He suspected the Eberth bacillus and not the plasmodium was responsible for most of the cases. He had no faith in the statistics attributing death so frequently to malaria in Brooklyn. North of the Chesapeake fatal forms were so rare that no health board should accept a death certificate signed malaria without investigation. The symptoms of malarial disease in temperate regions in this country were well defined and easily recognized, and the widespread belief in masked forms had no rational basis of support.

Little Malaria in New York City.— Dr. Walter B. James opened the discussion. He had been in the habit of looking for the malarial parasite for three years or more, and was able to confirm Laveran's investigations. He believed that malaria rarely originated in the city of New York. When he found the parasites it was usually in cases from outside the city, or above the thickly settled districts, or near the rivers

and large excavations. He had never found the parasite of estivo-autumnal fever, except in patients from the shipping districts. The form present about or in New York was that which produced tertian fever, the variety most easily diagnosticated clinically and microscopically. But he did not believe it was practical for most general practitioners to become so familiar with the microscope as to be able to diagnosticate thereby most doubtful cases of malaria. As a rule, in New York, when doctors sent him blood to be examined in cases of possible malaria, the parasites were not found. In other words, when the clinical history did not point rather plainly to malaria, the symptoms were not due to that disease.

Auto-Infection and Malaria.—Dr. A. Jacobi thought the chapter on malaria presented by Dr. Osler might better stand alone, yet he would make some remarks, in order that the printed programme might be carried out. While he agreed with Dr. James that the clinical diagnosis of malaria about New York was usually sufficiently clear, still the best diagnosticians the world over had welcomed this new aid in diagnosis. An important clinical means of recognizing malaria had already been mentioned. Few other diseases gave a temperature of 106° F. or more; at least, not so often. The swelling of the spleen was a valuable point. If in the first days the spleen could be felt below the ribs, the probability was the case was not one of typhoid. Ehrlich's test had been of some value to him in distinguishing between typhoid and malaria. The accumulation of putrefying material in the intestinal tract from overfeeding or improper feeding sometimes gave rise to a fever lasting several weeks if it were not attended to—an irregular rise of the temperature, which not infrequently was mistaken for typhoid. Rachitis was sometimes mistaken for malaria when it began more or less acutely. There were some cases of intense malarial poisoning without the usual paroxysms. They usually came from New Jersey or South Brooklyn, especially about Gowanus Bay, before that part of the city was as well sewered as it was to-day. Some of the subjects would have swelling of the spleen, anæmia, were scarcely able to drag themselves about. Although never having had an attack of fever and ague, an attack would develop after taking the first or second dose of quinine. When more quinine was given, the condition would disappear, confirming the diagnosis of malaria. The explanation had suggested itself to his mind that the quinine might have caused contraction of the spleen and entrance temporarily of a greater number of the plasmodia into the circulation, then an attack had occurred, but more quinine had effected a cure by driving the plasmodia from the blood.

New York Not Free from Malaria.—Dr. Egbert Le Fevre said that during the year 1896 they had made over five hundred examinations for the plasmodium malaria at Bellevue Hospital, and had found it in the large majority of the cases of malaria, about one hundred and two in number, in most instances the single or double group of the tertian variety. One patient, who had not lived out of the city, but on a fourth floor, showed nearly every fifth red blood corpuscle impregnated with the plasmodium, and his disease progressed to a fatal termination, in spite of quinine or other treatment. Eleven cases presented types of the plasmodium which they were unable to classify, but specimens had been kept for further study. In only a small proportion of all the cases had he been able to palpate the spleen, and he had been surprised at the number of cases which showed no increase in the size of that organ. A large percentage of the cases had developed within New York City; moreover, in the southern or old settled districts. Formerly he had been led to believe that most cases came from outside or from the outskirts of the city.

Dr. Simon Baruch referred to some experience he had had in the South, and expressed the opinion that the diagnosis of true malaria was more easily made than that of any other disease. He depended more upon the temperature than upon any other symptom. The chief feature was the great difference between the temperature at the beginning and acme of the paroxysm. It was very rare in any other disease to see the temperature rise in a few hours from normal or subnormal to 103° or 104° F. He thought that in the early stage of malaria enlargement of the spleen was so rare that he would pay no attention to it. Early in the '80's he had published a paper in the Medical Record, showing that out of one hundred and fifty deaths reported in Brooklyn as having occurred from malaria, in only thirty did the doctor who signed the certificate feel certain that death was due to malaria.

Dr. Osler, in closing, remarked further upon the rarity of death from malaria north of the Mason and Dixon line. He could not agree with the speakers who thought the spleen was not often enlarged. By the aid of position one could usually feel the spleen the first week. He was glad Dr. Jacobi had mentioned the occurrence of chill in morphine *habitués*. Dr. Osler had seen two cases of the kind, and in one the spleen could be distinctly palpated, but the parasite of malaria was absent, and they were puzzled as to the nature of the case until the patient admitted taking morphine. Ehrlich's reaction was not at all uncommon in malaria. Dr. Jacobi had expressed belief in intestinal infection, and had thus placed himself among the younger men of the profession. Dr. Osler was too old for that. Of course, it might occasionally occur. Malaria was rare in Baltimore and Philadelphia, and, it seemed, in New York, except in the outskirts.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Special Meeting, February 23, 1897.

Joseph E. Janvrin, M.D., President, in the Chair.

The Abuse of Medical Charity in Hospitals and Dispensaries.—The meeting was called at the written request of fifteen members for the special purpose of considering the abuse of medical charity in hospitals and dispensaries.

Dr. Stewart, member of the committee on hospitals and dispensaries, was called upon to make some introductory remarks. He said a number of men had been before the committee, leading it to believe that medical charity in hospitals and dispensaries was much abused, and probably every member of the association could give individual instances of such abuse, but it was desirable to have definite information and to hear suggestions for remedying the evil. The directors of two dispensaries had promised the committee to adopt any plan which the association might recommend for excluding from the dispensaries all who were not in need of charity. None wished to bar out the worthy. It was strange that in the neighborhood of some of the largest charities in the city he was asked to do more charity work than before these institutions had been started. He was unable to understand this, for there certainly were not more poor in that neighborhood than previously. The really poor man, the one who earned small wages, could not afford to go to such institutions, because it took too much time to wait his turn and he could not leave his work. Their chief patrons were the grocers and the butchers and a class of people who were well-to-do and could spend an hour or two waiting their turn among numerous other patients. A doctor in the

class for children said a woman had brought her child in a carriage, and it was learned that she was the wife of the largest wholesale liquor dealer in the city. One woman was advised to give her baby fresh air by riding on the ferryboat, and she replied that she intended to make a voyage to Europe, which she thought might be better. Certain of the dispensaries drew largely from the neighboring States, and physicians from the country had written him that it was only their best-to-do patients who could afford to go to the city, stay at hotels, and receive gratuitous medical treatment at dispensaries. He hoped to hear the experience of the members and suggestions looking toward a remedy.

Fifty per Cent. Able to Pay.—Dr. Freudenthal said there was no doubt that the evil of medical charity was growing daily. He had a class at the German Poliklinic, and, while the majority of patients going there was very poor, still there were some who were well able to pay. Indeed, on one day he had the Charity Organization Society investigate all of the patients attending his class for that day, and they found out of thirty-four patients that twenty were able to pay, while only fourteen were really poor. Something ought to be done to correct this, for no doubt it caused hardship for many physicians. It was necessary to have the aid of the whole profession in the city. The method adopted in London was the best one known to him. He believed that there everybody applying for attendance at a clinic had to bring a certificate from his landlord that he was poor. The certificate ought to be renewed every month or three months.

Dr. O'Meara stated several reasons why patients went to hospitals and dispensaries: 1. To consult a specialist. The physician who should send his patient for this purpose would lose him. He should go with him, and receive and carry out the suggestions of the specialist instead of leaving that to the patient. 2. The physician wishing to get rid of a disagreeable case sent it to the hospital or dispensary. 3. A patient being unable to pay the doctor's full fee, the latter sent him to a dispensary instead of to a young neighboring physician who would be glad to accept a smaller sum. 4. Subjects were sent to the hospital or dispensary by physicians because they could pay nothing whatever. In this instance as well as in the other, a young physician would treat the case as long as he was not very busy. 5. When the physician was unable to supply nurse, medicine, food, the patient had to go to a hospital, and this was proper. 6. When the patient pocketed his pride, his self-respect, and his money, and deliberately cheated the doctor by going to a dispensary or hospital. The speaker did not believe in doctors accepting pay for medical charity given patients in these institutions. He thought the method adopted in some foreign countries might stop the abuse of charity, the dispensary requiring the applicant to bring a certificate from the family doctor or from the clergyman, but the objection to this was that the clergyman was too ready to sign anything.

Dr. Louis Fischer had been connected with some dispensaries, and could say that while the abuse was great in some, in others it was present hardly at all. Teaching bodies must have material, but it need not be material which could pay. At his class for children the Charity Organization Society found some weeks that only about twelve per cent. were deserving of charity, other weeks fifty per cent. But the remedy rested with the physicians. If they would give their services gratuitously, the people would be fools not to accept. A fellow-practitioner had remonstrated with a wealthy man for going to a free medical institution. He replied by asking the doctor if he would not accept a box ticket to the opera. To do anything it must be through the combined efforts of all the medical societies of the city. It was not so much a question of dispensary abuse as of stealing fees from the physician. He would like to see a committee appointed to act with other societies. As to the suggestion that the landlord give a certificate, he would be foolish not to do so whether the patient were or were not poor, lest he lose his tenant.

Dr. Tarler thought it was the duty of this society to look after the interests of its members in this abuse, in that of lodges, in that of medical schools which had a way of getting their patients. There was a lying-in asylum in Broome Street which took confinement cases; the *World* newspaper sent out its list of free doctors; with it all there was little pay practice left for the starving physicians.

Dr. McGauran said a clergyman had told him recently that the doctor's occupation was gone in this city. Everybody went to the dispensary, where no pay was required. In his neighborhood, and he did not hesitate to say it was that of Roosevelt Hospital, patients who were able to pay him a fee of two dollars were visited by the dispensary physician free. Some people who acquired wealth in doubtful ways seemed to think they would gain heaven if only they founded a hospital. There was an institution on the east side which deserved mention, as well as the one on the west side. Recently a gentleman in the city had given a million dollars to take away all the confinement cases from the doctors in a large district, and the Academy of Medicine, or its chief officer in its name, had tendered him a vote of thanks. It was the physicians' fault, not that of the gentleman who was so generous as to make the gift. It was the heads of the profession who were to blame. They should be given to understand that they would receive none of our consultation practice. Seven years ago the speaker had written an article suggesting that a member of the association be appointed who should go around to all the dispensaries and keep watch of this charity abuse. Or the committee should be given power and they would go to Albany and seek such legislative action as might be suggested.

Educate the People.—Dr. L. F. Bishop said the large number of plans which had been suggested for controlling this abuse showed its wide extent and that no one of the plans was pre-eminently satisfactory. He suggested as one step the creating of a healthy public sentiment. A few months ago he had had occasion to speak to an audience of workingmen, and pointed out the injustice to the medical profession of accepting medical charity when one was able to pay for it, and no fewer than six of their number arose and made remarks endorsing this view, and a resolution was adopted pledging those present to do all they could to check this great wrong to the profession and to keep the people from abusing medical charity. It was more difficult to get those in the higher social and intellectual circles to take the correct view of the subject. Yet it could be done. A charitably disposed woman founded a small hospital and then all who had contributed proceeded to send their servants for free treatment. He was able to convince her of the wrong. A prominent officer of philanthropic societies, a student for years of social and political problems, was in the habit of sending people indiscriminately to medical charities. After having the wrong of so doing pointed out to him, he admitted that he had never before had any appreciation of the true ethics of medical charity. Among doctors there were those who sought to build up hospitals which would destroy the practice of the profession at large to the extent of thousands of dollars for the sake of the prestige which would increase their own income by tens. They were like the men who discovered the rubber trees and cut them down in order to obtain a portion of the sap. Each of us should with every opportunity point out

the fact that charity, except when required, was morally wrong.

Directors Willing.—Dr. Beaman Douglas believed that the directors of the medical institutions would be perfectly willing to act on any method generally recommended by the medical societies for the correction of the abuse of medical charity. It was not necessary to make this a subject of legislation, nor of public or newspaper discussion, but if practitioners came to an agreement among themselves the directors would cooperate with them. Dr. Douglas would suggest a sort of clearing-house arrangement, a central office, with a superintendent and such assistance as might be required, to which all of the dispensaries should report all of their cases for the day. Then, if a patient had been rejected at one dispensary because not worthy of charity, he could not go to another without the fact being known. One investigation would be sufficient for all districts. Out-of-town patients ought not to be treated. Let them go to their home charities.

Organize.—Dr. A. W. Warden thought the trouble with the doctors was that they were not organized. The keynote of to-day was organization. The commercial world, the business world in general, the laboring people, all classes were organized except the doctors. One thing which could be done was to put only such men into office in medical societies, etc., as were true to their fellow-practitioners. They had frequently elected men to office who were the greatest offenders in matters of medical charity.

The Managers to Blame.—Dr. Tull had had much to do with dispensaries the past ten years and believed that the managers were entirely to blame for the abuse of medical charity. If the doctor did not treat all the cases sent to his class, he was dismissed. In some dispensaries the Charity Organization Society investigated cases supposed to be unworthy of charity and made its report in ten days. The hospital abuse was even greater. He had treated a patient in one of these institutions who was worth $100,000 and he had received nothing. As to educating workingmen, pointing out to them the wrong of abusing medical charity, Dr. Bishop had more faith in human nature than he had.

Would Make the Abuse of Charity a Misdemeanor.—Dr. O'Donohue thought there had been too much beating about the bush; too much striking at the branches instead of at the trunk of the tree. Unless steps were taken to secure legislative action they might as well go home. Let it be declared a misdemeanor for any man receiving wages above a certain amount to apply for charity. Then select two or three offenders and make "a holy show of them," and there would be no trouble from the rest.

Seeking Fame.—Dr. J. S. Peterson thought the trouble lay not with the young physicians, but with certain older ones who hoped through hospital connections to become famous, to be looked up to as the "Great I Am." Again, patients were never asked whether they could afford to pay a doctor. If the dispensary physician should refuse to treat them, he would be requested to resign. The wife of a member of the fire department, who received a salary of perhaps $1,600, was receiving free treatment at a certain hospital dispensary. There was but one hospital in the city where the physician was allowed to operate on his own patients. The doctors of these institutions did not want it known that anybody else could operate except themselves. Indeed, the outside doctor was not allowed to see his patient except on public visiting-days.

Dr. Austin thought the committee on hospitals and dispensaries should go before the commission on the charter of Greater New York and have some provision made in the charter looking toward the prevention of the abuse of medical charity. The suggestion made by one speaker that the applicant at the dispensary be required to present a certificate from the landlord would not do here, for he knew of instances where landlords themselves and their families went to dispensaries for treatment. A remedy would never come through persuasion of hospital managers. Further to establish the abuse school doctors had been appointed. He had vaccinated a child which lived on Madison Avenue; the health-board physician thought the scar was too big and would exclude the child from school unless it was submitted to revaccination by him. If one had a boil he went to a hospital; if he coughed, an ambulance was sent for.

That Million-Dollar Gift.—Dr. Henry W. Berg thought that if there was any abuse of hospitals and dispensaries the doctors were to blame. He wished to call especial attention to the recent munificent gift of a philanthropist to a certain institution in the city, the donor having been led to think that it was necessary, probably by some medical man. But was it necessary? Dr. Berg believed that million dollars had been entirely misplaced, would be wasted, would do harm by serving to pauperize a large part of the community. How many cases of obstetrics in this city required free medical treatment? He thought not twenty-six thousand, which this immense sum would probably provide for. One-fifth that number was probably more nearly correct. If so, the rendering of gratuitous attendance to the other twenty thousand would simply tend to pauperize them. Let the matter be investigated by this society; let the number of confinements among the really needy in the city be ascertained, and if it were found to be not more than eight thousand, and he certainly thought it was not, then let some one go to this philanthropist, state the facts to him, and no doubt as a shrewd business man he would reduce the amount of his gift to correspond with the necessities of the case.

Not a Public Matter.—Dr. Thomas H. Manley thought the subject would have been simplified if the committee had come forward with a plan. There was no doubt that this abuse of public and private charity was very great and widespread, and, if allowed to grow as it had been doing, the masses of the medical profession would be reduced to poverty. It was not a matter for the public; it was not a matter for the legislature; it was not a matter for the public press. The first step to be taken was organization among the doctors themselves. Assuming that they had an organization, they must be disciplined. If the profession understood that the abuse was entirely because of, and was perpetuated by its own rank, the members could remedy it. He hoped that whatever was done would include the highest as well as the lowest hospitals, dispensaries, and schools. Let it be understood that the profession had the power to enforce its demands, and that he who offended would be ostracized. Reference had been made to the committee of the New York County Medical Society. He believed that committee was earnestly at work, but it would find the question a large one, and itself powerless unless supported by the united profession. He hoped the members of the association would be prepared for and meet an extra assessment which was necessary to carry on this work. A plan having been decided upon, let it be put into immediate force.

The Adelaide Hospital Troubles.—It is reported in an Adelaide newspaper that the council of the British Medical Association has notified Drs. Leith Napier and Ramsay Smith, who were hired to go from London to take the places of the medical staff of the Adelaide Hospital, that they would be dropped from the roll of membership of the British Medical Association at the next meeting of the council.

Correspondence.

LONDON LETTER.

(From our Special Correspondent.)

THE PRINCE OF WALES STARTS A HOSPITAL FUND TO COMMEMORATE THE QUEEN'S SIXTY YEARS' REIGN—MEDICAL SOCIETY—CLINICAL EVENING—LETTSOMIAN LECTURES—OBSTETRICAL SOCIETY'S ANNUAL MEETING—PATHOLOGICAL SOCIETY—THE PLAGUE—CONCURRENT EPIDEMICS AT DUBLIN—LORDS PLAYFAIR AND LISTER.

London, February 12, 1897.

I APPRISED you of the proposal to establish a hospital fund in commemoration of the Queen's record reign and the hope that the Prince of Wales would take the lead in such a scheme.

Well, the hope has been realized. The prince has circulated through the press a letter in which he describes the plan as "a project lying very near my heart." He tells us that in considering the figures furnished him he has been struck by the fact that the contributors to hospitals number less than one in one hundred of the population, and so he urges that it is "necessary to enlarge the area from which annual subscriptions are gathered." The prince does not believe this indicates indifference, but rather difficulty of choosing or of definite opportunity of giving, or a feeling that small amounts are not worth contributing. He proposes, therefore, to remedy this state of things, to afford every one the opportunity that may have been lacking, to save them the difficulty of choosing, and to collect subscriptions of one shilling and upward to "the Prince of Wales' Hospital Fund for London, to commemorate the sixtieth anniversary of the Queen's reign." In pursuance of the scheme the prince has associated with himself a representative committee the members of which are not managers of particular hospitals. Lord Rothschild has consented to be treasurer and the Bank of England has placed office accommodation at his disposal. The scheme is accordingly fairly launched, and has met with the cordial and often enthusiastic approval of the press and the people. In all directions we hear of plans for enabling people to pay in their shillings. Some plans are of course impracticable; many suggestions are obviously silly; but others are valuable though not, perhaps, well thought out. Among the most practicable, perhaps, is the issue of a shilling stamp, to be sold for this purpose at every post office. But there is some demur to this at headquarters. It would entail a little trouble and a trifling expense, but it would secure an army of willing collectors. What post-office clerk would not be willing to receive a sheet of shilling stamps for the Prince of Wales' fund and account for them separately from post-office accounts? This is but one of the schemes afloat, but it looks one of the best, and as the enthusiasm rises it may well carry the postmaster-general on its flood. Thus much as to the collection: then as to the distribution. It is proposed for the first year to rely on the distribution committee of the Hospital Sunday Fund. Here, if anywhere, is the weak spot in the scheme. The prince's committee might be trusted to distribute the funds, and of course, might at first advantageously avail themselves of the experience of the Sunday Fund committee. But the latter has not given universal satisfaction. I have more than once adverted to the manifest unfairness caused by its prejudices, and I shall be sorry if these prejudices are suffered to influence the new fund. There are certainly institutions as well as individuals that will refuse to help any fund which is to be distributed by the present Sunday Fund committee. The prince hopes to secure from £100,000 to £150,000 a year from persons who have hitherto been non-contributors. Should his hopes be realized, it will prove a splendid endowment for the hospitals, which, thus supported by the people, will become more national institutions than ever.

At the Medical Society's clinical evening on Monday there was an abundant supply of cases. Among them were two treated by Dr. George Stoker by his plan of applying oxygen. One of them was a specific ulcer of the leg, the other lupus of the nose, which had healed under the application of oxygen after curettage. One of the ulcers of the leg had been inoculated with staphylococci, a procedure to which much objection was made. It was also remarked that most ulcers of the leg would heal under cleanliness and rest, but Dr. Stoker did not admit this, and, considering the large number of people who have these ulcers for long periods, as any surgical out-patient room will show, I hardly venture to differ from him. He said the cases had been thus treated for years.

A curious case was shown by Mr. Morgan, that of a young man who had sustained a fracture of the anterior fossa of the skull from a fall, and though he had survived he had lost the sight over the temporal half of both eyes. It was conjectured that this curious result might be due to injury in the chiasma affecting the fibres coming from the nasal halves of both retinæ. The prognosis was regarded as unfavorable. There was a skiagraph of a sutured patella on view, showing the position of the suture. A case of fracture of the humerus was shown, in which an attempt to peg a fragment to the shaft had been made and the wound showed signs of infection with bacillus coli communis. Later the fragment was removed and good movement of the limb obtained.

A case of excision of the head of the radius for an old unreduced dislocation forward may be named, as the patient has perhaps as useful a joint as could have been expected if it had been possible to reduce the dislocation.

A man of fifty-two, whom Dr. Maguire supposed to have malignant disease of the lung, presented the following symptoms: swelling over the upper part of the left chest, over which the percussion note was very dull, the area of dulness being sharply defined; tubular breathing over this area, with equally sharply defined margins. There was dyspnœa, and it was said that at an earlier stage dysphagia had been present.

The society's Lettsomian lectures are this year being delivered by Dr. Haviland Hall, who has taken for his subject, "Diseases of the Throat and Nose in Relation to General Medicine." He describes in considerable detail the appearances which have been recorded as occurring in these parts in the course of various diseases.

At the annual meeting of the Obstetrical Society there was also an exhibition of specimens, including fibroma of ovary leading to ascites, lipoma removed from left lumbar region, fibroma of abdominal wall, fœtal monstrosity, etc., etc. A valedictory address was delivered by the president.

At the Pathological Society were shown specimens from cases of hemorrhagic diphtheria and ulcerative endocarditis affecting a malformed aortic valve, and a paper was read on Graves' disease with persistent thymus. This is rather a frequent condition, but what relation it bears to exophthalmic goitre is uncertain. We do not, in fact, know in what proportion the thymus is persistent, still less if it is generally present.

The plague bulks largely in the newspapers, and the views of various nations on quarantine are a frequent topic of conversation. An international conference is to be held shortly for considering precautionary measures, and the one subject to excite difference is quarantine. England will not depart from the system she has found efficient, and is reaping a fine

crop of abuse and even threats, in some continental journals. But these organs seem incapable of perceiving the shortcomings of their own people in sanitary matters.

The mortality of Dublin has risen to a point to excite keen anxiety—51 per 1,000 in the last week of January and 44.2 in the first of February—above double the average. Measles, scarlet fever, and whooping-cough, as I have already reported, are epidemic. Typhoid is also more prevalent than usual, and typhus appears in the returns. It is not common for several diseases to run a concurrent expidemic course, and the pressure on the hospital accommodation is most severe. Indeed, my advices speak of a complete break down. No doubt respiratory diseases are contributing largely to the mortality, for the weather has been most trying, but it is obvious that Dublin must prepare more isolation accommodation for infective diseases.

I may correct a mistake you have quoted from some of your contemporaries. Lord Playfair was never a medical man. He was professor of chemistry at Edinburgh. His doctorship was a German Ph.D. When first a candidate for Parliament, some of his political supporters tried to pass him off as a medical man, or at least one who had attended medical classes. His opponents of course made the most of this, and chaffed the "doctor" unmercifully on his supporters' pretensions, and suggested that if there were any foundation for the pretension he must be an "ornament of the great army of the plucked." All is said to be fair in elections.

Lord Lister is, then, the first medical man to receive a peerage. He is gazetted as "Baron Lister of Lyme Regis in the County of Dorset," but will be spoken of and addressed simply as Lord Lister.

NOTIFICATION OF TUBERCULOSIS.

To the Editor of the Medical Record

Sir: I have not seen the text of the recent order of the New York board of health regarding tuberculosis. It is possible that, as a result of its enforcement, some hardships might be temporarily imposed upon those so afflicted. This is, however, a matter of detail which is easily remedied. By your editorial I see that a number of letters have been received by you, indorsing your opposition to the measure. At the risk of being alone among your correspondents, I write to register my approval of the principle involved.

I seems to me a scarecrow statement of the Chicago physician you quote, that the liberties of the profession are being in any wise curtailed by a decree requiring the registry of tuberculous cases. That a quarantine should be enforced as in diphtheria and scarlet fever is, of course, out of the question; but that houses in which tuberculous cases are present should be recorded, so that the inmates may receive proper literature on the subject, and that the houses may at proper times be disinfected, is eminently proper. With a more general knowledge on the part of the public of the true nature of tuberculosis, such as this would bring about, we could hope for a sentiment soon which would insist on means for the proper care of railway cars and Pullmans and hotels; and, further, for the suppression of the habit of spitting on sidewalks and in public places. These reforms can only obtain in any general sense by special education, and the means inaugurated by the New York board of health is a movement in the right direction for the public good. Francis W. Gallagher, M.D.

El Paso, Tex., February 11 1897.

[Our correspondent is in the right, save in the suggestion that the board of health should do all the missionary work. The profession understands its duty in the premises, and can be trusted to perform it. No one would interfere with the board in its legitimate work of abating nuisances.—Ed.]

THE LEGAL RIGHTS OF THE CONSUMPTIVE.

To the Editor of the Medical Record

Sir: In your to-day's editorial on "The Health Board and Compulsory Reports," which is so thoroughly just in many respects, you seem to have overlooked several other aspects of the question which call for attention and consideration—namely, the legal and social rights of the patient, and the social and legal rights of the patient's friends. What if the patient does not wish to be reported? Has the physician a right—a legal right—to report the case against the wishes of the patient? As you and many others have already pointed out, the mere concurrence of a cough and tubercle bacilli are far from constituting tuberculosis. And even if it did, has not an otherwise capable, in body and mind useful man or woman a legal as well as social right to demand secrecy from the doctor concerning his or her ailment, in order that his or her social interests and the social interests of friends be not compromised? Has a consumptive fewer rights than a syphilitic, or even a criminal? The doctor is called on for advice, for help; and being called on for help, for advice, is it not going far beyond the limits of decency, to say nothing of privilege, to ask him to allow himself to be impressed into doing service as a detective, to the prejudice of his, in many instances, unsuspecting patient's interests? It is a hopeful sign, which speaks well for the medical profession, that so many of its members have protested against being manipulated as though they were mere reagents to be used for detecting bacilli, against the interests of their patients and that of their profession, in order to satiate the mistaken ambitions of bacilli hunters, who have apparently become oblivious to the macrocosm by too much special eye straining through the microscope and colored slides. Adolph Rupp, M.D.

406 West Thirty-Fourth Street,
February 27, 1897.

An Easy Method of Taking Plaster Casts.—The foot, for example, having been lightly smeared with vaseline, is quickly bandaged with an ordinary muslin and plaster-of-Paris bandage about two inches in width, which has been soaked in a hot solution of alum and water, in order to make it set quickly. The bandage must be squeezed as dry as possible before it is applied. The toes and heel are of course taken in, and the bandage is continued as far up the calf as is thought necessary. Not more than three thicknesses of bandage need cover any part. By a little careful squeezing, the bandage is pressed into the crevices between the toes, and, to strengthen the mould without making it more difficult to slit down, a little dry plaster of Paris is rubbed over the surface, avoiding the part where it is intended to cut down the mould. While the plaster is still moist, it is cut with a pair of scissors along the outer side of the leg and foot as far as the little toe, so that the mould can be easily drawn off the foot. The cut edges of the mould are at once approximated and fixed with strips of Mead's sticking-plaster. The mould is then set aside until it is thoroughly hardened; then it is oiled inside and filled with plaster of Paris and water mixed to such a consistency that it will run into all the crevices of the mould. When it has quite set, the strips of Mead's sticking-plaster are removed and the mould is peeled away from the cast.—Alan Mackay, *Intercolonial Medical Journal of Australasia*, September.

New Instruments.

A NEW EAR FORCEPS, EAR-SYRINGE TIP, AND OBTURATOR EAR SPECULUM.

By EMIL AMBERG, M.D.,

BOSTON, MASS.

Fig. 1 shows an angular ear forceps, with concavo-convex shanks and blades. The shanks are arranged

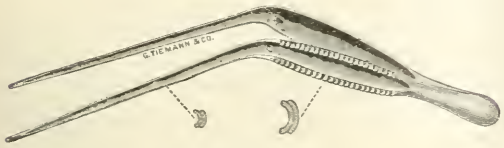

Fig. 1

so that the convex side of one of the shanks closes into the concave side of the other. The instrument is strong and light; furthermore, the shanks cannot slip one from another.

Fig. 2 illustrates a tip for an ear syringe, with a crescent-shaped opening at the end.. When introduced,

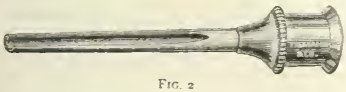

Fig. 2

the tip touches slightly the wall of the meatus. It proves to be better than the common tip for syringing out cerumen, because the stream of fluid is stronger than the stream produced with the old tip, and the fluid finds its way more readily behind the masses and returns more easily on the concave side of the tip.

Fig. 3 represents an ear speculum, armed with an obturator, resembling somewhat a vaginal speculum.

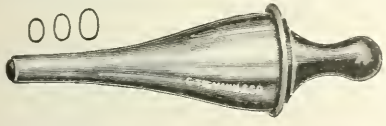

Fig. 3.

The tip of the instrument is to be oiled before being introduced. In cases in which the meatus is swollen, the introduction is less painful for the patient and easier for the physician than the introduction of an unarmed instrument. The instrument is made in different sizes.

These instruments are made by G. Tiemann & Co., New York City.

176 Charles Street.

Treatment of Hemorrhoids.—The technique of the operation may be summarized as follows: (1) Apply the clamp in the long axis of the hemorrhoid, so that the scar may be a radiating one, and thus avoid any chance of cicatricial stenosis. (2) Dip the distal end of the clamp well down, so as to include the mucous membrane of the hemorrhoid in its entire length, though only clamping off about one-third of its substance. Be sure that no skin is included, otherwise the subsequent œdema will be very great and time of recovery lengthened. (3) Sear the hemorrhoid slowly from above downward, layer by layer, the cautery being only at a dull red heat. By observing these precautions any subsequent hemorrhage is avoided. (4) Insert a tampon cannula, which must not be removed till expelled by the first stool.—Dr. Vaux, *The Canadian Practitioner*, December, 1896.

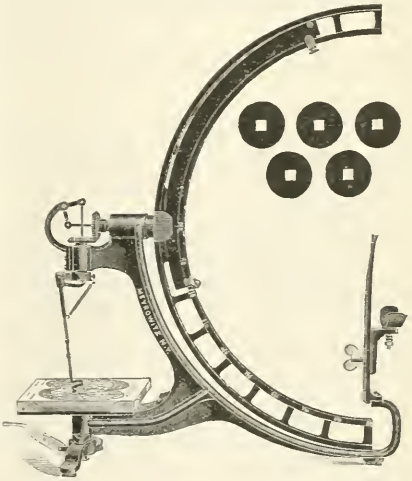
A NEW PERIMETER.

By FRANK D. SKEEL, M.D.,

NEW YORK.

The instrument here shown is the result of experiments extending over some years, in the endeavor to construct a perimeter which would be self-recording and at the same time simple in its construction. In the use of the ordinary instrument the examiner's attention is divided between watching the eye of the patient, the position of his own hand carrying the test object, in reading the graduations on two arcs, and in marking down the same on the chart.

In the instrument here described the reading of the graduations is entirely dispensed with, and the recording of the position of the test object simplified to the pressing of a lever. The general appearance of the instrument is plainly shown in the cut. The recording mechanism may need some explanation. The test object is carried on the thin extremity of a circular sliding wedge, which is fitted to the large arc and rotates with it. The posterior side of this wedge bears against a rod, which extends through the axis of the arc and transmits its motion to a vertical arm, carrying at its lower end a pencil. This vertical arm is connected to the axis of the large arc by means of a bevel gear, the rotation of the arc causing it to rotate on its own axis. It is also capable of motion toward



and from that axis. This latter motion is transmitted to it by the sliding of the circular wedge along the arc. When the test object is at zero or the centre of the visual field, the pencil occupies a position directly over the centre of the chart. When the test object is moved away from the centre of the field, it transmits to the pencil a similar motion over the chart, where the latter occupies at all times a position corresponding with that of the test object. When the test object has reached a position which the examiner wishes to record, he depresses a lever (shown at the back of the instrument below the chart), and a small dash is marked upon the chart. A line drawn through these dashes outlines the field. It is not necessary for the examiner to look at the chart until the operation of taking the field is finished. The chin rest is reversible for right and left, and adjustable for height.

I take great pleasure in acknowledging the intelligent co-operation of Mr. E. B. Meyrowitz in the construction of this instrument.

A SIMPLE METHOD OF TRANSFUSION.

By HUNTER P. COOPER, M.D.,

PROFESSOR OF ANATOMY AND CLINICAL SURGERY, ATLANTA MEDICAL COLLEGE, ATLANTA, GA.

Probably all who have made intravenous injections of a saline solution have been confronted by this difficulty: When there has been severe hemorrhage or profound shock, the median basilic vein is found empty and collapsed. In many cases of severe hemorrhage it is difficult to find the vein after making the incision over it, and much greater is the difficulty of inserting the needle into the vein in order to make the injection. Recently I attempted to inject a saline solution into the median basilic vein of a patient who was suffering profoundly from shock and loss of blood following resection of the rectum. As usual, I tied a bandage around the upper part of the arm, in order to obstruct the venous current and cause the median basilic vein to come into view; it was impossible to see it at all. I then made an incision over the situation of the vein, and finally exposed it thoroughly. It was apparently completely empty and collapsed. I attempted to puncture it with my needle, in order to make the injection; but the point of the needle passed into the posterior wall of the vein, and I had to withdraw it and try at a little higher point. At this effort the needle penetrated entirely through the vein. I then gave up any further attempt and resorted to subcutaneous injections over different parts of the body. I have had this

same difficulty a number of times, on account of the collapsed condition of the vein. It is to meet this condition that I have devised the needle, of which the accompanying cut is a fair representation, and the following technique:

The needle is simply a probe-pointed needle, with an opening in the middle of the end and a constriction above the end; in every other respect it is like an ordinary aspirating needle. Having exposed the vein and dissected it up from the tissues underneath it for a full inch, apply pressure forceps to it an inch apart; then cut through the vein at a point near the distal compression forceps, insert the probe-pointed needle into the proximal cut end of the vein, and secure it in the vein by a silk ligature; tie tightly around the needle at the constricted portion of the same; then remove the compression forceps and make the injection. After the injection, ligate both of the cut ends with catgut and close up the wound.

This method possesses advantages over the old method, for the reason that it is always a perfectly simple matter to get into the vein, whether it is full or empty. It has advantages over the use of saline fluid subcutaneously, as, in the first place, it is painless; and, in the second place, the fluid goes directly to the heart, without any absorption having to take place, as in the subcutaneous method.

Retrospect.—In our discussions upon antitoxins and other disputed questions of the day, it is well to look back seventy-five years, as Moritz Schmidt said in his opening address at the late congress of medical and natural sciences, held at Frankfort-on-the-Main, and contemplate physicians of that day discussing the correctness of the theory of the circulation. In seventy-five years from now men may smile at us, but no disgrace can ever attach itself to honest convictions based upon experience and honestly and fearlessly expressed.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 27, 1897:

	Cases.	Deaths.
Tuberculosis	226	127
Typhoid fever	9	7
Scarlet fever	126	17
Cerebro-spinal meningitis	5	6
Measles	133	8
Diphtheria	211	21
Laryngeal diphtheria (croup)	5	2
Chicken-pox	18	0

The Country Practitioner and the City Hospitals.—In a paper by Dr. M. W. Knight (*The Atlantic Medical Weekly*, January 23d, the country practitioner is urged to operate more frequently, especially in the commoner forms of surgical cases, instead of referring his clients to the city hospitals or to specialists. "Personally," he says, "my relations for the most part with city consultants have been exceedingly pleasant: and I prize their friendship, their courtesy, and their counsel. I have, however, met one or two whom I trust it will be my good fortune never to meet again. More than one man of no extraordinary mental endowment, through wealth, influence, and combination and culmination of favorable circumstances, has been heard from in our cities and in our hospitals who, had he been obliged to locate in some rural district, without these necessary adjuncts to success, would probably have never earned his daily bread. More than one country practitioner, could he compete on merit and ability alone, would prove a formidable rival to his city contemporary."

The All-Round Specialist.—When a man claims to know everything and be equally competent in all branches of work, not hesitating to operate on the eye and internal organs, he should be engaged as the general agent for some of the products which are being advertised as sure cures for consumption, catarrh, cancer, and the like.—*National Medical Review.*

"Doctor of Refraction" is what travelling opticians now call themselves out West, and by the use of the title of doctor are in a position to mislead those to whom they sell their wares. A bill is before the legislature of this State whose enaction would place the refracting "doctor" on about the same legal level with the physician.

The Dispensary Abuse is in its infancy in Denver, and the *Colorado Medical Journal* makes a plea that it be kept down, as it now can be, by an agreement among the physicians to maintain but a single general institution. We trust the Denver doctors may be wise enough to act upon this advice and not wait until the dispensary grows greater than its creator and destroys it.

Early Diabetes.—Dr. Wilson (*The Lancet*, November 14, 1896) relates an instance of diabetes at the age of four years. The urine contained six grains of sugar to the ounce, and the child died in coma.

Headache of nasal origin commonly is present on awaking, whereas headache due to eyestrain comes no later in the day after using the eyes.—*Denver Medical Times.*

ADVANCES IN THE TREATMENT OF CHRONIC CARDIAC DISEASE.[1]

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

HITHERTO rest has been considered by the best clinicians as our most reliable resource in many cases in which cardiac failure was evident. Now we are led to believe by the reports and observations of many physicians that passive or active exercises are essential frequently to the best results attainable in similar cases.

For many years already, massage treatment, according to the method of Linn and his followers, has unquestionably proved beneficial. Later it was found, in certain cases which had notably improved with massage and passive movements, that walking up gradually inclined roads, according to Oertel's system, would still further increase cardiac power. For some years past, however, there has been a growing enthusiasm on the part of an increasing number of people in favor of Schott's system of treatment of chronic cardiac disease with resisted movements and stimulating baths.

Despite these facts, which I shall elaborate later, we should not lose sight of the truth, that rest in bed is imperative at times and for a certain period in the treatment of cardiac failure, if we wish to promote recovery or even amelioration.

Take, for example, those cases of cardiac dilatation already marked by the gallop rhythm, intense dyspnœa, cyanosis, a weak, rapid, irregular pulse, œdema of the lower extremities, and note what remarkable results may occasionally be obtained with rest. These symptoms, most if not all, I have seen thus disappear. That is true in a degree, we are sometimes disposed to say, but was not the good result effected far more by drugs than by rest? To test it, drugs have been sparingly given—if at all—and the beneficial effects of rest were soon most marked; whereas, when the patient was going about he was either not benefited, or was gradually growing worse. What is true in ordinary chronic cases is still more evident in those instances in which there is suspicion of an acute process being grafted on the old lesion. If acute endocardial inflammation should perceptibly be present at all, then absolute rest and quiet must be insisted on.

Avoidance of cold is also of great service. No one perhaps more than Sibson has brought the importance of this matter to our minds. I am satisfied that drugs are of secondary importance at such times, yet we should not altogether underrate their value: and if there be even a slight increase of precordial pain, with some change in the cardiac murmurs and cardiac action, it is wisdom to order moderate doses of the salicylates. Of course, there are those who reject their influence. The statement is made that they do not prevent the liability to any localized inflammatory development: others say that their influence is negative even when the inflammatory condition is present. Still, as the salicylates are strongly advised by some writers, it is not doing one's whole duty to the patient to withhold them or some suitable substitute. For my part, I prefer in many such cases of heart trouble, in which the underlying rheumatic dyscrasia is clear, a combination of chloride of ammonium and acetate of potassium. Indeed, I am confident from frequent experience that in the treatment of rheumatic manifestations this is a more valuable combination than the salicylates. Perhaps the pain may not be always so quickly allayed as with the salicylates, but the future course of the disease is preferable. The dose of these drugs given by me is ten grains of each, every two hours for one or several days, in a suitable menstruum. When the symptoms improve, as they usually do quite rapidly, I diminish the frequency of the dose. I consider this a matter of practical moment so to influence the rheumatic poison at times as to prevent any fresh intracardiac development.

Rest with the laboring man is one thing; rest with the man of refinement and easy mode of life is quite different. In the latter cases the physical strength has not been tried, as a rule, by daily bodily effort: their work—if work there has been—has been of the brain rather than of the body. Recuperation should come not necessarily from absolute repose for a time in the direction of outlay of their bodily energies, but rather by giving up close and arduous mental occupation for a time, or indeed by proper, judicious physical exercises and limitations of their diet.

In these cases particularly, I have seen good results proceed from close attention to dietary rules and from exercises already referred to, of the Linn, Schott, or Oertel systems.

Many such cases never indeed come under medical treatment of a strict, severe kind until serious or fatal symptoms develop. The signs of marked cardiac insufficiency show themselves without any evident valvular disease, by weak, rapid, or slow pulse, cyanosis, and œdema of the legs.

In many instances there is no dropsy, and even the physical signs of dilatation, as manifested by palpation and percussion, are difficult or impossible to determine conclusively. In some cases there is considerable corpulence or obesity, and there is doubtless already fatty overgrowth around the heart. In others, the patients are spare of body, of delicate or weak frames. In these we often have slow pulse with occasional syncopal attacks without apparent sufficient cause, or pain over the precordial region with extension down the left arm in the nature of pseudo-angina.

Whenever fatty degeneration is suspected, as in the first division particularly, exercises are doubtless at times of great value, if properly governed with learned and judicious care. In the others, however, I am still of the belief that neither exercises nor cardiac tonics —with the exception of strychnine—are of much avail. Here again we must insist upon complete rest in bed, and frequent stimulation with ammonia, chloric ether, and alcohol in small doses. Some authors speak of the utility of increasing doses of nitroglycerin, particularly if the pulse be hard and tense; but, judging

[1] Read before the Practitioners' Society of New York, February 5, 1897.

by my own experience, the very slow pulse with tendency to syncope does not often accompany hypertension unless it be of the spurious kind, to which Ewart has directed attention.

The kneading of muscles in the corpulent cases, when performed carefully and for short periods of time each day by a well-trained masseur, combined with moderate passive movements of the limbs, according to the patient's strength, gives good results.

After a while, a few days or as many weeks, the system of Schott may be attempted. In this system, as I have said, regular exercises are given daily, and at the time of the transmitted movements there should be moderate resistance on the part of the patient to the efforts made by the manipulator. All the limbs are exercised in rotation, and the amount of exercise given should be limited, according to the feelings of the patient or by the watchful interpretation of the attendant. Upon the slightest evidence of cardiac palpitation, distress, or dyspnœa, the exercises should be stopped. The results thus obtained are often surprisingly beneficial.

We all admit the advantage accruing to patients affected with chronic heart disorder, even when compensation is impaired, of keeping the skin in good condition. Hence baths are serviceable, provided the temperature is not too elevated and they are of short duration and not given too often. The stimulating baths, therefore, of Nauheim, with their large percentage of carbonic acid and of the chlorides of sodium and calcium, are of undoubted efficacy. Given alternately at the same time with "resistance gymnastics," they show wonderful results.

But are these baths really more useful than other baths of a different composition? This subject is still *sub judice*, and already it has been claimed that equally good effects may be obtained with the rational employment of natural sulphur waters. Be that as it may, it seems quite certain that in many cases, after a single or a few stimulating baths or resistant exercises, the heart will show great changes.

In hypertrophous dilatation, when the heart had been accurately determined as to its size by methods of physical exploration, and notably auscultatory percussion, previous to the Schott treatment, subsequent measurement showed positive and considerable diminution in size. This decrease was not always lasting —at least in the beginning—to its full extent; still the permanent decrease in size after a more or less prolonged treatment was often unmistakable. With it came a stronger, more regular heart action, and a fuller, vigorous pulse, as well as a disappearance of many threatening symptoms.

The Oertel system seems to be especially adapted to those who previously have eaten or drunk to excess, and who also have fatty overgrowth thus brought about. As a rule, it should only be employed with those who have had sufficient strength to go through with the Schott treatment advantageously, not to speak of the still milder one of Linn, with kneading and passive movements.

In Oertel's system the graduated exercises consist in walking up hills of slight or more considerable elevations, and for a shorter or longer distance, depending upon the patient's strength and ability to compass them without undue fatigue.

According to Oertel's statements and those of others, the heart thus rapidly acquires an increased degree of strength. In both systems—those of Schott and Oertel —the result is to bring more blood to the heart muscle, and thus promote its healthy nutrition.

In either of these treatments it is obvious that the most intelligent supervision of the patient should be constantly brought to bear, and only thoroughly trained competent manipulators employed. Again, it is also essential that an accurate diagnosis of the case should be previously made. I am perfectly confident myself that whenever there is any inflammatory action going on, no matter how insidious it may be, such exercises can only be productive of harm to the patient.

In those cases in which degenerative processes of the heart muscle are present, as when there is reason to believe that thrombosis of the coronary arteries exists, the greatest care and circumspection should be had in order to avoid positive injury. It is desirable, however, that close study and observation of Schott's treatment particularly (as it seems one better adapted to a large number of cases of heart failure) be instituted among us, that we may be able to give the benefit of it in its most important features to very many sufferers who are wholly unable for major reasons to go to Bad Nauheim. Be it here said that Schott himself—all to his honor—has wisely insisted that there was nothing so special in his treatment that it could not be carried out wisely elsewhere. While we should be prepared, in view of excellent clinical reports from prominent physicians, to accept the benefits of the Schott treatment for certain well-defined cases, we should not yet be willing to adopt it, as apparently some are inclined to do, as the ordinary treatment of chronic cardiac disease. Whenever there is marked degeneration of the vascular supply of the heart or of the myocardium, we should interdict this treatment as possibly leading to disastrous results, in extreme conditions even to heart rupture itself.

Chronic interstitial nephritis, however, does not apparently contraindicate its careful employment. The presence of an aneurism, on the other hand, undoubtedly would. We have learned obviously from the favorable reports of this treatment that have come to us that there are numerous cases in which there may be much benefit derived from properly resisted movements and the diversion of a large amount of blood into the capillaries of the skin at a time when ordinary active exercise should still be interdicted. An overloaded, hyperdistended, unduly engorged right ventricle may thus be perhaps relieved of intraventricular pressure when blood letting would be the only other alternative. This treatment, as has been said (Lauder Brunton), seems to occupy a somewhat intermediate position between massage treatment and that of Oertel in climbing mountains. To sum up, I should be disposed to accept as a proper guide for medical men at present the hope expressed by G. Herschell, of London, that they will "pause before they introduce into their routine practice a method of treatment the effects of which are so little known, and the indications for which are so little understood."

The question of proper diet for cases of cardiac disease is an important and difficult one to solve at times. Whenever cardiac insufficiency begins to show itself, the veins of the stomach are more or less engorged and the gastric fluids act less efficiently, no doubt from changes produced in their quantity and composition. The result is that nausea frequently and occasionally vomiting result from the use of different alimentary substances. As a consequence we have to contend against an extreme distaste for food. Under these circumstances it is indicated to allow those things which are nutritious and yet most readily assimilated. Among these we would especially recommend predigested beef, or beef and bread; peptonized milk, milk with Vichy or lime water; kumyss, matzoon, egg albumen with water, whey, light broths of different kinds, meat jellies, curds, beef juice. The quantities of any one of these liquid or semisolid foods given at a single meal should be small, but frequently repeated. Gradually, as the quantity of food is increased with each meal, the intervals between repasts may judiciously be lengthened. Later on as the patient im-

proves, a different dietary should be provided, and here we must use our knowledge of the patient's position, habits, and surroundings somewhat to control us. For the hospital patients, it is often wisdom not to limit them to light diet too closely, or to give them much either of farinaceous food or drink, such as tea or coffee.

Already the day laborer—whether we have to do with a man or woman—has lived much on bread and tea and small quantities of poor meat indifferently cooked. Provide them with food well prepared, underdone roasted or broiled beef, or mutton in suitable amounts, and limit the starches, while allowing them to drink freely of milk and less freely of water, and it will often change their condition for the better. On the other hand, the cutting off of proteid substances in excess and the strict limitation of fluids among a class of well-to-do patients are often strongly indicated.

In these instances it is that Oertel's system in part achieves excellent results at times. This is to limit the amount of fluids and lessen the amount and kind of food previously taken. In general terms, for the large class of cases in which the diet previously had been unobjectionable for a person in good health, and yet for a condition of chronic heart disease with lack of compensation should be controlled, we would say: give, after the acute stage or serious symptoms have passed, moderately of fish, eggs, fowl, and broiled and roasted meat. The latter—beef or mutton, partly cooked on a broiler and then scraped with a not too sharp knife—will be found digestible and invigorating: salt and pepper may be added in small quantities.

According to Oertel, corroborated in great degree by Andrew Clarke, the quantity of liquid allowed in twenty-four hours, including what is taken with the solid food, should not exceed thirty-six ounces. If habit be enforced in this direction, not only will obesity diminish, but the blood will become smaller in quantity and denser. With the diminution of the volume of blood and its change in density, the heart is relieved from internal pressure which had interfered with the action, and hence the pulse becomes soon more regular and fuller. What is true in regard to the change in quantity and quality of blood as proving beneficial to the patient is also true about the diminution of corpulence. Manifestly, if this general condition is present, it will be found as a rule that there is fatty overgrowth of the heart, and likewise, with the progress of the case, partial degeneration of the cardiac muscular fibres, owing to the deposit of fat in their structure in larger or smaller degree. Now, then, this condition manifestly interferes greatly with cardiac power. Diminish the fluids allowed and fat will decrease, and hence the patient's circulation will little by little acquire vigor and tone. Again, fluid given in large quantity, either at mealtime or else very soon after it, is bad, because it dilutes the gastric fluid and hence interferes notably with stomachal digestion.

Flatulence and dyspepsia are both occasioned by indulgence in some kinds of starchy food; therefore, potatoes, fresh bread, and many cereals should be prohibited. Dry toast, some form of very light cracker, occasionally rice in different forms, prepared foods, ordinarily called baby's food, of well-recognized utility, are not objectionable at times, but, on the contrary, should be allowed. In regard to alcoholic stimulants we would say, in the first place, that in treating urgent acute disturbances they are most valuable. At times cardiac distress, palpitations, dyspnœa—and even precordial pain—are more quickly relieved with a hot toddy than in almost any other way. But when it comes to their habitual use, then opinions differ. I am quite convinced that in the majority of cases wines at meals are undesirable; and yet there are some persons so accustomed to their glass of sherry or claret at lunch and dinner that in not allowing them I believe I am doing positive injury. As a rule, however, small quantities of whiskey or old brandy, preferably the former at meals, and at bedtime added to milk or egg beaten up, or following broth or beef tea in a little water, promote digestion or quiet repose at night. Among people of middle life, and especially among those of advanced years, I cannot insist too strongly on the importance of my statement.

Whenever the alcoholic stimulants produce temporary or more durable flushing of the face, headache, or stomachal distress, the quantity should be diminished notably, but their use should not be wholly abandoned. It is remarkable to notice the small amounts of whiskey, brandy, or even wine which will at times distinctly ameliorate a condition of cardiac failure. While insisting upon the intelligent moderate use of alcohol in the treatment of certain cases of chronic cardiac disease, I should throw out a warning note against any excessive use of it, or any form of it which interferes with stomachal digestion. As an article of diet, alcohol in small quantity, three or four times daily, and in a more or less continuous manner, acts favorably many times: taken in excess, as a routine matter, it becomes a notable depressant of the general system, and promotes those inflammatory or degenerative changes in vessels and cardiac muscle which we have greatest reason to fear.

Combined with the catarrh of the stomach, in many of our old cardiac cases there are often deficient absorption from the intestinal canal and pronounced costiveness. With these symptoms we readily discover passive congestion of the liver, with or without slight tenderness on pressure, and a decided subicteric hue of the conjunctivæ. Aperients of different nature, counter-irritation over the liver, more or less severe in form, moderate doses of mineral acids internally, are all useful in helping to relieve the engorged portal circulation and bile ducts. But what, to my mind, is a great improvement to-day in our manner of treating these symptoms is the return to a judicious use of mercurials. Calomel in fractional doses (one-tenth or one-twentieth of a grain every hour) with a little bicarbonate of sodium until the bowels have moved, and repeated after a few days, is frequently most valuable in increasing the bulk of the urine and promoting the regularity and force of the pulse. Of course the gums should be watched to prevent possible salivation, and I cannot insist too strongly on the great care that should be exercised in stopping the use of calomel in these cases whenever the gums become at all tender on pressure or the incisor teeth unduly sensitive.

I have had a most distressing and painful stomatitis occur when I had not been sufficiently careful to consider the probability of its development. What is true of calomel in respect of its utility is also but in a less degree true of bichloride of mercury. In small repeated doses the bichloride has been advised, either alone or combined with the tincture of the chloride of iron. I have not used this combination sufficiently to form a perfect judgment in regard to it; still, from what I do know, I consider it inferior to calomel as a diuretic and cardiac restorative in acute distress. Personal experience now of a prolonged period and in very many cases of all kinds makes me very emphatic when it is a question of blue mass in the treatment of these cases of slight or advanced cardiac failure. In corpulent men or women, of advanced or middle life, it acts like a charm at times. You may have tried all the cardiac tonics in suitable doses for many days with very moderate or practically no result. You may have given the ordinary saline aperients until you are of the opinion that the bowels are thoroughly and efficiently evacuated, without good results, and yet

afterward I have known a few doses of blue mass, either at bedtime or several times during the day, make the patient feel like a new person. The color improved; the strength braced up; the urine increased in volume; the pulse was stronger; the heart action more regular; the breathing was less oppressed —every symptom, in short, rapidly grew better. It is certain that one has not so much to dread salivation from blue mass as from calomel, which is a great advantage; and, on the other hand, I have found it quite as satisfactory, indeed more so, than calomel in the relief of all cardiac symptoms of a distressing kind for which I first prescribed. After a few doses of mass hydrarg., either two or there grains morning and evening, or five grains at bedtime for three or four successive nights, followed or not by Rochelle salts and Vichy in the morning, I have been able time and again to make effective use of my cardiac tonics when previously, as I have said, they had been relatively of little use. Not only is the mercurial of service in instances of corpulent people with cardiac insufficiency, allied or not with a very appreciable degree of cardiac dilatation, but it is also very useful at times in men of spare habit and nervous constitution, between forty-five and sixty years of age, when general arterial fibrosis is more or less clearly defined. These cases are often affected with symptoms of a gouty kidney (interstitial nephritis), with a certain degree of hypertrophous dilatation of the heart, and slightly corded temporal or radial arteries. Sometimes high tension is clearly made out; again, the tension seems to be of the spurious sort, and not infrequently, when the heart action is decidedly weakened and when there are dizzy turns with pains in the head, feelings of numbness and formication in the upper and lower limbs, itchy sensations, slight evidence of cutaneous eczema, and a general nervousness, restlessness, and irritability, the pulse is weak, depressible, and slightly irregular, or even intermittent. Even in these cases I give mercurials repeatedly, with the happiest result, and cannot emphasize too forcibly my firm belief in their utility. Sometimes the acid taste in the mouth, the concentrated urine with a considerable amount of urates or uric acid contained in it, appear to call primarily for the alkalies in moderate doses; and yet I have found as a matter of experience that frequent small doses of nux vomica during the day, blue mass at night, and rest and a regulated diet do much better, and bring about a change which alkaline treatment was quite unable to accomplish.

I cannot but mention here also with much emphasis that the condition of the urine in these cases often varies greatly and is often deceptive as regards the condition of the patient. I have seen such cases when the urine passed had a low specific gravity, contained a very small amount of albumin and a moderate number of granular and hyaline casts; I have known these patients to have urine of wholly different character, viz., high specific gravity, no casts, no albumin, increased amount of uric acid, bulk about normal. In either instance the mercurial has been of service in relieving distressing symptoms. In the first class of cases I am of the opinion that the arterial spasm was indirectly broken up by its use. In the second class, I believe the hepatic engorgement was especially relieved by its action. Not infrequently in cases in which the pulse has been unduly hard and tense, and called apparently for the use of nitroglycerin, I have found that after giving nitroglycerin for a while in increasing doses, and without getting all the good effects I desired, the employment of blue mass in the way indicated by me was distinctly advantageous. Perhaps its use was not immediately apparent, but if persisted in for a few days its beneficial results were obvious, and once shown they were more lasting than those caused by the use of nitroglycerin. With the latter drug we must confess frequently that while we obtain the most brilliant and satisfactory effects by its use, and while we continne to employ it, just so soon as we give it up the heart relapses speedly into its old weakness, hypertension in the arteries recurs, albumin is again found in notable quantity in the urine, and precordial anxiety or distress *sine dolore* comes back. This is not true with the use of the mercurials as a rule. When decided benefit is derived from their use, this gratifying result is more lasting, and the patient is able, perhaps, to get about and do for himself for quite a little while without experiencing a number of annoying or painful symptoms, which also occasion more or less incapacity. Sometimes in these cases, especially when there has been notable œdema of the lower extremities, or indeed effused fluid in the thorax or abdomen, just in proportion as these dropsical signs disappear under the use of the mercurial, the blood pressure in the arteries increases. This increased tension must be regarded, of course, under these circumstances, as a proof of the good results produced and certainly does not in my judgment indicate the use of nitroglycerin, but rather that of strychnine or small doses of digitalis, employed with great care and constant watchfulness.

The fact of arterial hypotension or hypertension has been at times a somewhat troublesome thing to determine accurately. Of course, in many instances, by tactile appreciation and with expert use of the sphygmograph we can unquestionably determine its presence. Moreover, in almost all cases we can obtain corroborative evidence of hypertension in the arteries by listening carefully to the aortic sound of the heart. Whenever there is hyperarterial tension there is accentuated or augmented aortic sound as heard by the ear in auscultation. Of course we must avoid misinterpretation at times and considering the spurious kind as being evidence of true arterial tension. Ewart, as already stated, has directed attention to this source of error, and at the same time has given us certain rules for our guidance in order to detect and avoid it. After all, however, there are some cases in which these different means of exploration leave us in much doubt as to the presence or absence of hypertension in the arteries, and certainly we cannot thus have any exact measure of slight amounts in excess or differences of tension.

Now, in physiological experiments for a long while past, different more or less complicated instruments have been used in order to measure arterial tension in animals. In man, for purposes of clinical research, several of these instruments have been tried, but by reason either of the difficulty of making use of them or because their report, so to speak, was not thoroughly satisfactory, their use has usually been abandoned. There is one, however, viz., the sphygmomanometer of Potain, of Paris, which seems to me to have considerable practical value, and which I would recommend for clinical use in hospital wards. While Potain's instrument is open to objections, somewhat in the same manner by analogy that certain hæmoglobinometers are, yet on the whole it has its value and is a quite satisfactory addition to our medical armamentarium.

Having recognized hypertension in the arteries, how should we combat it? Should arterial hypertension invariably be treated? Under what circumstances may we properly ignore it, in the sense of not treating it actively, but rather of considering its presence of good augury? It seems to me that the somewhat prevalent idea among practitioners of medicine, that we should invariably endeavor to diminish by medication exaggerated arterial tension whenever present in chronic cardiac disease, is a regrettable mistake of judgment. With more careful consideration

of the pathological conditions involved, I am confident this erroneous belief will diminish or disappear. In many cases the hypertension of the visible arteries like the radials or temporals is merely indicative of a permanent change which is present in them and also in the peripheral arteries elsewhere—and particularly the kidneys. Now, then, to try by means of drugs to change notably this condition in a permanent manner is quite futile, and may be positively injurious to the patient. If the heart be doing its duty fairly well, if there be no threatening or unpleasant symptoms apparent, why interfere or attempt to control its action merely because the pulse is hypertense as compared with the normal? A certain degree of hypertension is desirable in general arterial fibrosis, and why? Simply because it indicates that the heart is still able to do its necessary work efficiently. Diminish this tension somewhat and you lessen, doubtless, the peripheral resistance to the heart's action by arterial dilatation. And yet so far as the wellbeing of the patient is concerned, it remains apparently the same. There were no unpleasant symptoms, it may be, prior to the moderate use of nitroglycerin; there are no unpleasant symptoms after its moderate use. On the other hand, if there be notable dyspnœa, or palpitations, or headache, or nausea, or repeated vomiting, accompanying even slight hypertension of the radial pulse, nitroglycerin is frequently most useful, given in small or moderate or large doses more or less frequently repeated. In many such cases we have truly wonderful results from this remarkable drug. These results may be but temporary, and as soon as the sufficient dose is diminished or interrupted the distressing or dangerous symptoms of cardiac insufficiency rapidly return. Judiciously managed, the drug is capable, as we all know, of yielding lasting benefit.

It may be by allowing the heart for a while to cope successfully with the obstacle in front of it, through dilatation of the peripheral arteries and until with other means we restore in a measure its strength and dynamic power. It may be also that of itself it acts as a real cardiac stimulant or tonic.[1] With regard to this, opinions are divided. For my part, I believe nitroglycerin acts at times in both directions: first, as a cardiac stimulant; second, as a vascular dilator.

The Pathology and Treatment of Chilblains.—Wright (*Lancet*, January 30, 1897, p. 303) has undertaken to show that chilblains are dependent upon a condition of defective blood coagulability and that relief can be afforded by improving the state of the blood. A study of the blood in ten cases of chilblains showed that coagulation resulted in from four and one-half to thirteen minutes, while in healthy persons such a result took place in three or four minutes. This fact is related to the following other facts: the superior liability of children to chilblains; the proneness of chilblains to occur in persons who give a history of either nose bleed or urticaria; the occurrence of chilbains in persons characterized by a lymphatic habit of body; and the not infrequent occurrence of chilblains in persons who are subjects of the malarial cachexia and in hæmophilic families. On the basis of these facts the obvious indication is to augment the coagulability of the blood. This may be effectually accomplished by the administration two or three times a day of from ten to twenty grains of crystalline calcium chloride, or half that amount of the desiccated chloride, twice or thrice daily, together with the avoidance of sour fruits, alcohol, and excessive quantities of fluid. Complete cure was brought about as soon as sufficient augmentation of coagulability had been achieved.

OPERATIVE SURGERY AT THE CITY HOSPITAL, WITH A COMPLETED REPORT ON THE STUDY OF WOUND INFECTION.

By GEORGE EMERSON BREWER, M.D.,

ATTENDING SURGEON, CITY HOSPITAL; ASSISTANT DEMONSTRATOR OF ANATOMY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

AND

PHILIP HANSON HISS, M.D.,

ASSISTANT IN BACTERIOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS; ASSISTANT BACTERIOLOGIST TO THE NEW YORK CITY BOARD OF HEALTH.

ONE year ago the writer of the clinical portion of this report presented a paper entitled "Operative Surgery at the City Hospital, with a Preliminary Report on the Study of Wound Infection," to the Harvard Medical Society of this city. This communication consisted, first, in an analysis of the 152 operated cases, occurring during his service of six months in the year 1895; and second, in a more or less complete report of a systematic series of experiments, undertaken with a view to improving the surgical techniques of the hospital. It is the object of this paper to make a very brief report of the operative work done in a service of five months in 1896, and to give the results of further study upon the subject of wound infection, including a complete bacteriological investigation.

The number of cases operated upon during the period covered by this report was 109. Of the operations, 9 were upon the head, 11 upon the neck, 7 upon the thorax, 8 upon the abdomen, 20 in the ischio-rectal region, 8 in the inguinal region, 10 upon the upper and 34 upon the lower extremity. The 9 operations upon the head were: 1 excision of the superior maxilla for sarcoma; 2 osteo-plastic resections of the skull, 1 for abscess of the brain and 1 for epilepsy; 2 cysts of the scalp; 3 cases of necrosis of the lower jaw; and 1 epithelioma of the nose. Of the 11 operations upon the neck, 7 were for cellulitis or abscess, 3 for tuberculous glands, and 1 for ligation of the external carotid artery. Upon the thorax there were 2 cases of resection of the rib for empyema, 1 partial resection of the clavicle for deformity following fracture, 3 operations for cellulitis or abscess, and 1 for caries of the spine. Of the 8 operations upon the abdomen, 7 were laparotomies, 4 for appendicitis, 1 exploratory operation for carcinoma of the colon, 1 inguinal colostomy for carcinoma of the rectum, 1 for large ventral hernia, and 1 for extensive left retroperitoneal abscess. In the ischio-rectal region there were 8 cases of fistula, 4 of abscess, 8 of hemorrhoids. In the inguinal region there were 1 case of varicocele, 1 of strangulated femoral hernia, 1 Halsted and 7 Bassini operations for the radical cure of inguinal rupture. Of the operations upon the upper extremity, 2 were for cellulitis and abscess, 3 for necrosis, 1 excision of a tuberculous wrist, 1 for compound fracture of the humerus, 1 for carbuncle of the hand, 1 for extraction of a foreign body in the hand, and 1 for exploration of the elbow. Upon the lower extremity there were 6 operations for cellulitis and abscess, 9 for varicose veins, 2 excisions for tuberculous arthritis of the knee, 1 amputation of the thigh, 1 amputation of the knee, 2 cases of hallux valgus, 1 glandular tumor of the groin, 2 cases of necrosis of the metatarsus, 1 necrosis of the femur, 1 necrosis of the tibia, 2 Thiersch grafts for ulcer of the leg, 1 extensive exploratory operation for gunshot wound in the pelvis, 1 for non-union of the leg, 1 for talipes equinus, 1 exploratory operation on the knee, and 1 for a tuberculous hip.

Of the 109 patients operated upon, 87 were discharged cured, 5 improved, 6 not improved, 9 died, and 2 are convalescent, but still in the hospital. Of the 9 deaths which occurred in the cases operated upon, only 1 can be fairly attributed to operation, and that was in a

case of osteoplastic resection of the skull for epilepsy, which will be more fully considered in the second portion of this paper. In 1 other case death was possibly hastened by operation. The case was a tuberculous one, and the operation consisted simply in opening and draining a small pocket of pus in the neck. Of the remaining 7, 2 died of acute lobar pneumonia, 1 of septic leptomeningitis, 1 of tetanus and septicæmia, 1 of acute miliary tuberculosis, and 1 of gangrene of the lung, all of these conditions existing before operative measures were undertaken, although in one instance the existence of a pneumonia had undoubtedly been overlooked.

Study of Wound Infection.—In the first report, published one year ago, to which reference has already been made, it was stated that during the month of May, 1895, when the writer first went on duty at the hospital, forty-three patients were subjected to operative treatment. Of these, six were presumably in an aseptic condition at the time of operation, and the wounds should have healed by primary union. The records, however, show that in every instance suppuration occurred, and although in a few cases, which were infected at the time of operation, asepsis was established and the resulting wounds were absolutely free from pus, the showing, as regards our techniques, was extremely bad. The following is the plan adopted during this period. The patient was brought to the operating-table, and the region to be operated upon was scrubbed for three or four minutes with green soap and hot water, a sterilized brush being used. The skin was then douched with ether, and finally with a solution of bichloride of mercury (1 to 2,000). The patient was covered with dry sterilized towels. The dressings, gowns, sheets, etc., were sterilized for one hour in the Arnold sterilizer. The instruments were boiled in a one-per-cent. solution of sodium carbonate, and then placed in a 1 to 40 carbolic solution. The ligature and suture material was treated by immersion for half an hour in a 1 to 20 carbolic solution, and then boiled for one hour in a 1 to 80 carbolic solution. The operator and all assistants were clothed in sterilized gowns, and their hands prepared by scrubbing with soap and water for three or four minutes and then immersing them in a 1 to 2,000 bichloride solution for about two minutes. Irrigation was with a sterilized normal salt solution. As soon as it became evident that our results were imperfect, a systematic attempt was made to improve our techniques. The problem was a difficult one, for many reasons. In the first place, it was found upon investigation that over eighty per cent. of the patients admitted to our wards were in a wretched condition of malnutrition from syphilis, tuberculosis, chronic alcoholism, or insufficient food. In the second place, by the system of rotation in the hospital, our entire house staff was changed every six weeks. Our operating-room was small, badly ventilated, and wholly unprovided with running water or any of the ordinary modern appliances. The sterilizing apparatus was of the crudest form, and the methods of preparing the ligature and suture material were conspicuously faulty. The first improvement introduced was in the method of preparing the hands; and then followed experiments with a view to perfecting the sterilization of the patient's skin; after this, numerous changes in the methods of sterilizing the dressings, sponges, silk, catgut, etc. Accidental contamination of the hands, instruments, and dressings received careful attention. Accompanying these changes, a progressive improvement in our results was noted, but we were never able to reduce the number of infections occurring in clean cases below thirty-three per cent., until, as a last resort, the plan of operating without assistants was introduced. The results were strikingly satisfactory, only two small stitch infections occurring in the ten clean cases operated upon during the last month. The infection of clean cases was, therefore, in six months, reduced from one hundred per cent. to twenty per cent. The report closed with the statement that it was the writer's intention to continue these experiments, and, if necessary, to inaugurate a series of bacteriological investigations, with a view to locating and removing any sources of infection which had, up to this time, escaped observation; after which it might be possible to gather some data which would help to solve the question of how much (if any) unavoidable suppuration might be expected in this class of cases.

As the result of the work which was done during the year 1895 at the hospital and our improved results, a very general interest was manifested on the part of the house staff and nurses toward further improvement. At the same time, an effort was being made by the visiting staff to get new and modern operating-rooms. This effort was ably seconded by our superintendent, and, as a result, the Commissioners of Charities provided us with two new operating-rooms, fully equipped with the best and most modern appliances. A well-trained operating-room nurse was appointed, and she, with her assistants, assumed full charge of the preparation of all dressings, ligature and suture material, the care of all instruments and operating-room furniture.

During the writer's spring service of two months at the hospital, no case of infection occurred in a patient whose wound area was aseptic at the time of operation. This period of immunity from infection also extended well into the autumn service until toward the close of the third month, when one small stitch abscess occurred. A rigid investigation was instituted to account for this unexpected break in our hitherto perfectly clean record. All of those present at the operation were rigidly questioned, and it was learned that the senior assistant, who handled the instruments and suture material, developed, twenty-four hours after the operation, a well-marked paronychia, which disabled him for several weeks; and it was thought that the suture was contaminated by his finger, which was undoubtedly infected at the time of operation. Our methods at this time may be best determined by reading the following rules, which were printed and conspicuously posted in the operating-room and all the surgical wards of the hospital, and followed to the letter during the writer's service:

"Preparation of patient: When possible, a hot bath shall be given the day before the operation, followed by shaving and scrubbing the part for two minutes; soap poultice over night. The following morning, rescrubbing for ten minutes, after which a wet bichloride gauze dressing shall be applied (1 to 1,000); this to be done only by the head nurse in the ward, after thorough sterilization of the hands.

"On the operating-table, the dressings shall be removed and the part washed by the house surgeon for one minute with soap and sterilized water, a pledget of sterilized cotton being used instead of a brush; then douched with ether, alcohol, and a sterilized salt solution.

"Sterilized dry towels to be used around wound area.

"The operator, his assistants, and the operating-room nurse shall wear freshly sterilized gowns. Gauze caps shall be worn in every aseptic case by those in immediate contact with the wound area.

"The hands of the operator, his assistants, and the operating-room nurse shall be prepared in the following manner:

"After cleaning the nails with soap, water, and a sterilized nail cleaner, the hands must be scrubbed for

five minutes, with frequent changes of hot water, a sterilized brush being used; then scrubbed for one minute in absolute alcohol, then immersed for three minutes in a 1 to 1,000 solution of bichloride of mercury.

"Or, after scrubbing with soap and hot water for five minutes, immersion in a saturated solution of permanganate of potassium for at least one minute, in a saturated solution of oxalic acid until the stain of the permanganate is removed, and finally in a 1 to 1,000 bichloride solution for three minutes.

"The ligature and suture material shall be removed from the bottles and handled only by the senior assistant surgeon; dressings and sponges only by the operating-room nurse.

"The head nurse of the ward shall superintend the moving of the patient, the adjustment of the blankets and other unsterilized coverings, assist the etherizer, and be prepared when necessary to assist or take the place of the operating room nurse.

"No departure from these rules will be allowed without the permission of the house surgeon."

One week after this first mishap, the second and only serious case of infection occurred. The patient was referred to the writer by Dr. E. L. Fisher, of the neurological department of the hospital, for an exploratory operation for epilepsy. The skull was opened by means of a large omega-shaped bone flap, and a small area of chronic leptomeningitis found, which had resulted in a firm adhesion between the dura and pia over the motor area. This adhesion was separated, and a small piece of gold foil introduced. The temperature remained at or near the normal line for five days, when a sudden rise occurred, following a fall out of bed. Pressure symptoms soon developed, and upon opening the wound, which had apparently united perfectly, a teaspoonful of thin pus escaped. The patient subsequently died, evidently from a septic meningitis, although no autopsy could be obtained. This unfortunate result, following so closely upon the other, led to a more than ordinarily careful inquiry. The house staff and operating-room nurse were called together, and each one questioned in regard to every step of the operation and the sterilization of the material used, without eliciting any fact which would account for the infection. The writer then determined to have a thorough bacteriological examination made of our material and methods, and through the courtesy of Dr. Cheesman, of the bacteriological laboratory of the College of Physicians and Surgeons, was enabled to obtain the services of the associate author of this report, who was asked to come to the hospital as frequently as necessary, to make a thorough study of our methods, and to suggest any changes in our technique which would insure more ample protection against wound infection.

Bacteriological Report.—The writer of the clinical portion of this report has detailed the various methods of hand disinfection and general technique employed during his service, before the institution of the bacteriological investigations, and it alone remains for the writer of this portion of the paper to give, in some detail, the results of these investigations and the modification in technique resulting therefrom.

The section of the hospital allotted to operative surgery is divided into two operating-rooms, by wooden partitions which extend only half way to the ceiling. Between these partitions runs a public passageway, opening at either end into a hall. The doors of this passage are seldom closed, which allows draughts of air, which may carry in dust and infected lint from the wards opening on to the general halls, and thus contaminate the air of the operating-rooms. The walls and ceiling of the operating-rooms are smoothly painted, the floor is new and of hard wood, the operating furniture is all of metal and glass, the plumbing and fittings are new, all admitting of thorough disinfection. The walls and ceilings are washed down with 1 to 1,000 bichloride regularly, thrice a week; the floors, table, and other furniture, after each operation. To test in some wise the purity of the air, gelatin plates were exposed in several parts of the room during an operation. The plate exposed on a table near the hall partition showed, from a fifteen-minute exposure, 24 colonies of bacteria and 8 moulds. A plate placed on the instrument table gave, for the same exposure, 20 colonies of bacteria and 6 moulds. Another plate, exposed for fifteen minutes near a slightly open window, gave 16 colonies and 5 moulds. To compare these, plates were exposed for five minutes in male ward 7 and female ward 10. These showed, for ward 7, an average of 57 colonies of bacteria and 14 moulds; and for ward 10, an average of 12 colonies of bacteria and 2 moulds.

The air of the operating-room, although comparatively free from germs, is thus shown to be a very possible source of infection and contamination, not so much probably to the comparatively small wound area, as to the large surfaces exposed to it by the instrument and suture trays and dishes, in which the previously sterilized water may be left unprotected or unchanged for varying lengths of time, or even during a long operation. To protect these in some degree, at first the use of a sterilized towel was suggested, to cover them when not in use; and later, a raised covered frame with flaps was devised for the purpose, thus obviating as much as possible any air contamination.

Attention was also called to the possible source of infection from the use of wide-neck agate-ware pitchers, for carrying the normal salt solution and sterilized water to the operating-table. The lips of the pitcher often came into contact with the clothing of the extra nurses and orderlies, who were not in sterilized gowns. The only change at present adopted in this technique is that a sterilized towel is kept over the pitcher when being carried to and from the operating-table.

The method of hand disinfection in use at the time of the first investigation has already been described. To test its efficacy, numerous scrapings were taken from around and under the nails and from between the fingers of those participating in the operation, and transferred to bouillon tubes. Within twenty-four hours after being placed in the incubator, at 37° C., two of the tubes showed growth—one from the nail scrapings of the operating surgeon and one from those of the house surgeon. Within forty-eight hours another tube inoculated with the nail scrapings developed a growth, the delay in development being probably due to the inhibitory action of the bichloride. This disinfectant, as is now believed, forms an albuminate with the organisms or becomes attached to them in sufficient quantity to delay or inhibit their development when transferred to a nutrient medium; hence, it is customary to treat them with a solution of ammonium sulphide, to neutralize this action, before disinfection can be positively said to be complete, growth often occurring after such treatment when none is shown in the control tubes. In these experiments this was not done, the growths occurring without this treatment.

The second series of cultures was taken in the same manner as the first, after the preparation of the hands with potassium permanganate and oxalic acid and subsequent immersion in a bichloride solution. This time the hands were treated with a solution of ammonium sulphide. Cultures were taken both before and after this treatment, and with the following results: The scrapings from between the fingers of the hand of the attending surgeon, which had been treated with ammonium sulphide, showed a growth. The nail scrapings from the fingers of the house surgeon, who

operated, showed growth within twenty-four hours, both with and without the ammonium-sulphide treatment. The scrapings from the nails of the operating-room nurse gave a growth after ammonium-sulphide treatment in twenty-four hours; and from a scraping taken before this treatment, in seventy-two hours.

As these disinfection methods gave rather unsatisfactory results, it was decided to try the simple method recommended by Fürbringer. In this, all dirt is removed from around and beneath the nails with an orange-wood stick, and the nails and hands are then thoroughly brushed with soap and hot water for five minutes, then thoroughly washed and brushed in eighty-per-cent. alcohol for two minutes, and then soaked in a three-per-cent. carbolic solution for one minute. The results obtained were more satisfactory than those given by the two previous methods. Growth was obtained from the hand of but one person. Since this experiment this method has been regularly used, and the results seem fully to justify its continuance.

At the time of the experiments in hand disinfection, clippings from the dressings, gauze, sponges, towels, sheets, gowns, caps, catgut, silk, silkworm gut, etc., were taken and transferred to bouillon tubes; also scrapings from the wound area of the patient. The various catguts, silkworm guts, in use, the towels, sponges, gowns, caps, etc., gave uniformly no growth in the several experiments. The tubes inoculated with the scrapings of the wound area of the patient remained sterile. A needle from one of the open trays, in use during the operation, gave a growth in bouillon. Growth was also obtained from one piece of gauze dressing taken from the central layer in the sterilizing box; pieces from the outside layer gave no growth.

The method of sterilizing the gauze dressings, gowns, towels, sponges, etc., in use at this time, was to expose them to ten pounds' pressure in the Sprague steam sterilizer, manufactured by Richard Kny & Co., for one-half hour on three consecutive days. This procedure seemed faulty, as it implied a fractional sterilization, which could be of little or no value, as no nutrient medium and little moisture are present in which resistant spores may develop into vulnerable vegetation forms, and thus be killed at the subsequent exposure to high temperature. Sterilization for one hour on one day only was recommended, and in subsequent experiments no growth was obtained.

To test the autoclaves, it was deemed advisable to carry on a series of experiments, using well-known organisms, to determine more accurately the time of exposure to ten pounds' pressure necessary for purposes of ordinary sterilization. Staphylococcus pyogenes aureus was chosen to represent the pyogenic organisms, and bacillus subtilis the resistant spore formers. The staphylococcus is usually destroyed by ten minutes' exposure to a temperature of from 56° to 58° C., while the subtilis spores are very resistant to high temperatures. It has been the custom, in using the autoclaves, to run the pressure up to ten pounds immediately, not allowing the contained air to be heated and driven off through the petcock and the steam to stream through until the temperature reached 100° C. When this is not done, the temperature and pressure do not run up together; the requisite ten pounds' pressure may be indicated, while the thermometer may not register the corresponding 115.6° C. for some time; while, on the other hand, if the steam is allowed to stream through for a few minutes and the petcock then closed, the pressure and temperature run up together.

The following experiments illustrate this. In these experiments tubes containing subtilis spore threads and tubes containing pieces of gauze soaked in a bouillon culture of staphylococcus pyogenes aureus were placed in the sterilizing-boxes—a tube of each in the centre of the box with gauze dressings surrounding, and a tube of each near the top of the box outside the dressings. Two sets of spore threads were used from different cultures of bacillus subtilis. One is indicated as *A* and the other as *B*. The threads were, immediately after the sterilization, transferred to gelatine plates, and the staphylococcus gauze to tubes of bouillon. In the first experiment the sterilizing-box containing the tubes was placed in the autoclave, the petcock closed immediately, and the pressure run up to ten pounds, the steam not being allowed to stream through. At the end of twenty minutes the pressure was reduced and the box removed. The plates gave the following results: Spore thread *A*, inside, growth in twenty-four hours; outside, growth in forty-eight hours. Spore thread *B*, inside, growth in thirty-six hours; outside, growth in forty-eight hours.

Culture *B* throughout seemed more susceptible to heat than *A*, and its growth was always delayed. In the next experiment, after turning on the steam the petcock was allowed to remain open for five minutes and the steam to stream through. The cock was then closed, and the pressure run up to ten pounds for fifteen minutes, with the following result: Spore thread *A*, inside, growth in forty-eight hours; outside, growth in sixty hours. Spore thread *B*, inside, growth in sixty hours; outside, no growth.

The delay shown in the appearance of all the growths around these threads when subjected to ten pounds' pressure for only fifteen instead of twenty minutes demonstrates the advisability of allowing the steam to stream through before running up the pressure. The next experiment allowed the steam to stream through for five minutes and the pressure to remain at ten pounds for twenty-five minutes. Growth was shown by only one thread, after ninety-six hours. In the last experiment the box was in the autoclave one hour. For five minutes of this time the steam was allowed to stream through, and for the remainder the pressure was at ten pounds. None of these threads showed growth. All of the tubes containing the infected staphylococcus gauze were placed in the incubator at 37° C., but none of them developed a growth.

As the result, therefore, of our bacteriological investigation, three sources of infection were found to be possible in the technique hitherto employed. These were: first, from the dressings; second, from the hands of the operator and his assistants; and third, from the air. To remedy the first, one hour of continuous sterilization with live steam, under ten pounds' pressure, was adopted. To remedy the second, the Fürbringer method of preparing the hands was employed (which gave us the nearest approach to perfect sterilization), and, in addition, all assistants wore rubber gloves, which had been rendered sterile by boiling for five minutes in a one-per-cent. solution of sodium carbonate, and subsequently kept sealed in jars of bichloride. To remedy the third, no adequate means could be devised, although we adopted the plan of keeping our instrument trays and solutions under tents of sterilized muslin supported on wire frames.

During these experiments and for the remaining six weeks of the service, only two other cases occurred which gave the slightest evidence of suppuration, and these were two small areas of infection which surrounded a single cutaneous stitch which had been left for fourteen days in the tissues under the first dressing. In both instances the temperature had been normal, and neither patient had complained of discomfort.

In conclusion, it may be said that, although the results of our operative work during the year 1896 were by no means perfect, yet they show a marked improvement over those of 1895, as will be seen from the summary of general results given below:

Of the 109 patients operated upon, 64 were infected at the time of operation, 43 were clean, in 2 no inci-

sion was made. Of the infected cases, in 17 an attempt was made to establish asepsis and bring about healing by first intention or granulation without suppuration, and in 13 instances, or seventy-six per cent., we were successful. In the 43 aseptic cases a serious infection occurred in but 1 instance. If, however, we include the 3 cases of single stitch infection, the whole number showing evidences of infection was 4, leaving 39, or ninety-one per cent., in which perfect asepsis was maintained.

I am aware that many surgeons may regard our methods as extreme and our techniques as unnecessarily exaggerated. But when one considers the wretched physical condition of the majority of the patients we are called upon to treat at the City Hospital, and the fact that such cases react, both locally and generally, to an amount of infection which would cause little or no disturbance in a vigorous or healthy individual, it is evident that, to obtain results which will compare favorably with those obtained in private practice or in hospitals where the more fortunate classes are treated, we must seek by every possible means to guard against the known sources of infection. In the writer's opinion, in a well-equipped hospital, with a well-trained staff, it is possible to exclude all sources of wound infection but three. These are the hands of the operator, the skin of the patient, and contamination through the air. As in our own experiments with sixteen cultures growth was obtained from the hand of but one individual when the Fürbringer method was employed, and as the chances of such a growth being due to a pyogenic organism are exremely remote, by employing this method and by the use of sterilized rubber gloves by all of the assistants the percentage of infection from this source must be extremely small. The frequent presence in the skin of the staphylococcus epidermidis albus, demonstrated by Welch, furnishes an occasional source of infection which it is wholly impossible to remove. Wound infection from this source is favored by rough handling of the parts, by undue tension of sutures, and by allowing them to remain too long in the tissues. To avoid contamination from the air in an operating-room situated as ours is at present, it is the opinion of the writers that the instrument trays and solutions should be as thoroughly protected as possible, and that the number of onlookers, in unsterilized apparel, should be reduced to the minimum.

Muscular Wryneck.—Dr. Kader (*Beiträge z. klin. Chir.*, vol. xvii., p. 207), having had an opportunity of studying thirty-four cases of wryneck, makes the following interesting report of his investigations. In twenty-one of these cases the sterno-mastoid muscle was removed and microscopically examined. 1. In muscular wryneck there exists an interstitial fibrous myositis of the sterno-mastoid muscle. 2. This myositis consists in excessive growth of the connective tissue of the muscle and degeneration of the muscular parenchyma, its place being taken by newly formed connective tissue, so that not only is the stroma thickened, but large patches are found which are partially or wholly connective tissue. 3. The myositis may affect the whole muscle or only a part of it. 4. The myositis has a chronic, progressive course, although its onset is marked by a more acute character. 5. The transformation of the newly formed granulation tissue into old cicatricial tissue produces the contraction atrophy and rigidity of the sterno-mastoid. 6. Other muscles besides the sterno-mastoid may be affected. If so, the same process takes place in them. 7. The alterations sometimes observed in the nerves are secondary to those of the muscles, and are to be looked upon as caused by the extension to the nerves of the inflammation going on in the muscle.

THE TECHNIQUE OF BLOOD STUDY AND EXPERIMENTS IN THE PHYSIOLOGICAL CHEMISTRY OF LEUCOCYTES—A STUDY IN CELL TISSUES AND THEIR SIGNIFICANCE IN TUBERCULOSIS.[1]

By A. MANSFIELD HOLMES, A.M., M.D.,

DENVER, COL.,

LECTURER ON HÆMATOLOGY IN THE UNIVERSITY OF COLORADO; HÆMATOLOGIST TO ST. JOSEPH'S HOSPITAL; MEMBER OF DENVER AND ARAPAHOE, AND COLORADO STATE MEDICAL SOCIETIES, ETC.

Disease, like a living organism, develops from an invisible beginning. In other words, it develops from an invisible entity into a visible entity. It is generally believed that there is a latent stage in the development of all diseases. In many diseases this is known as the prodrome, which sooner or later develops into the active stage. Tuberculosis, in its development, is no exception to the general rule. In the so-called active stage of tuberculosis there are disintegration and wasting of tissues. Hence it is customary to date the beginning of the active stage from the first apparent evidence of disintegration. If we trace tuberculosis backward from the stage of visible disintegration, we shall sooner or later reach a period in its development in which the evidence of disintegration disappears from the patient. We thus pass from the visible into the invisible realm. It is our purpose now to investigate this invisible realm. The microscope reveals the fact that the disease in this so-called latent stage is in progress, though not apparent to the senses. That which is understood as the predisposition is now seen in the blood elements as a condition. In the active stage of the disease we were studying the patient; now we are studying his leucocytes. And I find that the law that brings about disintegration in the larger organism has already brought about the same process in the leucocytes at an earlier date. Hence I believe that I have shown that there is no latent stage of the disease. It is all active. Therefore I believe that which is termed the predisposition to disease is not latency. It is an invisible activity, which is either advancing, unconsciously to the patient, toward visible activity, or convalescing toward the normal state.

With this preliminary statement of the subject, I will proceed to give it more in detail. The material out of which I have formulated my deductions has been obtained from a study of more than one hundred cases. Hence, with nature's proof, I feel justified in claiming that in tuberculosis the condition of the individual can be ascertained from the appearance of the leucocytes of his blood.

The clinical study of disease in the larger animal organism has been reduced to a scientific technique. An important principle in the study of pathological conditions is based upon the fact that a change in the appearance of an organism is preceded by a change in its functions. Hence, to be able to distinguish disease from the appearance of tissues, it is necessary to become familiar with these tissues when their functions are normal. In other words, we must be familiar with normal histological conditions before we can distinguish pathological conditions. Therefore the technique of the clinical study of disease in the larger animal organism or in its gross tissues is followed out according to uniform methods. The temperature, pulse, and respiration reveal the degree of functional activity. Auscultation, percussion, and inspection reveal definite conditions of the organs. Chemistry determines the condition of the secretions and excretions. The family and personal histories help to reveal tendencies which may have been transmitted by

[1] Read before the Second Pan-American Medical Congress, in the City of Mexico, November 17, 1896.

the laws of heredity or acquired through the medium of uncongenial environment.

In a previous article,[1] I made the statement that the larger animal organism has a true prototype in the leucocytes of its own blood. Hence, since the condition of the larger organism can be ascertained through a careful and systematic technique, I therefore claim that the condition of the leucocytes can also be ascertained, if a proper technique is adopted.

A study of the blood requires an intimate acquaintance with cell tissues. And these are so delicate that the microscope and staining fluids must be brought into use before they can be distinguished. Hence, if disease can be recognized from the appearance of gross tissues, it should be equally true of cell tissues. Therefore, if an examination of the blood is made in any particular disease and repeated observations demonstrate that definite blood conditions are uniformly present, the condition of the cell tissues should be accepted as evidence of diagnostic value, equal with the physical signs observed when studying the larger organism.

Furthermore, the tissues of the larger organism are constructed of and replenished by leucocytes that undergo differentiation. Hence, if it is possible to ascertain the condition of the leucocytes before they become differentiated into tissue cells, it will reveal the predisposition of the larger animal organism before the actual condition exists, or at least before it can be recognized by the natural eye. On the other hand, before we can scientifically utilize the appearance of leucocytes in the diagnosis of disease, it must be demonstrated that these conditions and appearances uniformly exist in the cells, and that they bear a definite relation to the larger organism. This, therefore, necessitates a study of cell tissues, and before studying them it will be necessary to review

The Technique.—In the ordinary study of blood an exact technique is unimportant. But, if it is our purpose to detect the physiological or pathological conditions of leucocytes from the delicate and peculiar reaction of their tissues to stains, it is of the greatest importance to adopt a technique that is accurate and uniform. This technique, then, should be adhered to in every detail, if we expect to secure results that will admit of comparison. The technique which I have adopted is divided into the following steps: (*A*) Preparing the blood films: (*B*) fixing; (*C*) staining; (*D*) mounting; and (*E*) studying the mounted specimen.

(*A*) Preparation of films: This is by no means an unimportant factor. Unless it is properly performed, all subsequent work will be useless, and the specimen will lead to erroneous conclusions. In fact, a failure in any part of the work will render the specimen useless. The following points should be carefully observed: The cover glasses should be absolutely clean, dry, and polished. They should be handled with forceps to prevent moisture from collecting on the surface, which prevents the blood from properly spreading. Fine lint fibres often act in the same manner. The finger of the patient is then cleaned antiseptically and pricked with a sterilized needle. For this purpose Emmet's cervical needle, with triangular point, is quite satisfactory. The drop of blood should then be used immediately, and a fresh drop for each film. A cover glass held in forceps is touched to the apex of the drop of blood, the drop coming in contact with the centre of the glass. This is immediately placed upon another cover glass. If the cover glasses are clean, dry, and polished, the blood immediately begins to spread and continues uniformly in every direction. If the drop does not spread satisfactorily, it is evident that there were moisture, lint fibres, or foreign substance on one or both of the cover glasses. As soon as the spreading ceases, the cover glasses should be immediately separated by pulling them in parallel planes, in opposite directions. The blood spreads by capillary attraction, and in no case should pressure be used. Too much blood or not enough will give poor films. And when films are poorly prepared they should be destroyed immediately, and another trial should be made. An ideal film consists of a single layer of cells.

Artificial Injury to Cells. — Crushed corpuscles are often observed in the study of prepared specimens, and may result from two causes: (*a*) from a faulty technique; and (*b*) from a disintegration resulting from a feeble organization of the cell tissues. The first is the result of a post-mortem injury to the cell. The second is due to an ante-mortem disintegration, and always signifies a weak or diseased cell, endowed with feeble vitality. If the corpuscles are injured in the process of preparation, fragments and débris will always be seen uniformly extending from the injured cell, in the opposite direction from which the cover glass was separated from its companion. A practised eye readily distinguishes these varieties; and unless they can be so distinguished, erroneous opinions may be formed.

(*B*) Fixing: As a fixing solution, I use the following: Absolute alcohol and Squibb's ether, equal parts, to which I add five per cent. of distilled water. The uniform time for fixation is two minutes. I have observed that a freshly prepared fixing solution never gives results equally as good as an older solution. Fresh solutions have a tendency to crenate red corpuscles and to produce vacuolation in the hæmoglobin. I have also observed that the longer the solution is used, the better are the results. I can account for this improvement only on the ground that the solution is rendered less injurious to the red cells by evaporation, the ether evaporating more quickly than the alcohol or water. Hence, when a new fixing solution is prepared, I allow it to stand for a few hours exposed to the air before using it. It is also important to note that in films fixed immediately after being taken, the red cells are less liable to crenate and the structure of the cells is more perfectly preserved.

(*C*) Staining: Almost all animal tissues possess great affinity for stains. This is true of cell tissues as well as of the gross tissues of the animal organism.

Classification of Dyes.—There are two important classes into which dyes are divided: 1, according to their chemical reaction; 2, according to their behavior to tissues. The first is subdivided into (*a*) acid, (*b*) basic, and (*c*) neutral dyes. The second is subdivided into (*a*) substantive and (*b*) adjective dyes. Of the first class, the majority belong to the acid and basic groups. Neutral dyes are rare. Substantive dyes are absorbed by the tissue directly from the staining solution. Adjective dyes require the intervention of a mordant, which aids in staining the tissues by forming insoluble compounds with the coloring matter, or by serving as a medium on which the staining solution acts.

Classification of Tissues.—All tissues, animal and vegetable, may be classified according to their staining properties under four heads: (*a*) Oxyphile tissues react to acid stains; (*b*) basophile tissues react to basic stains; (*c*) amphophile tissues react neither to acid or to basic stains, or to both; (*d*) neutrophile tissues remain indifferent both to acid and to basic stains. A successful technique should enable us to recognize and to classify tissues according to these varieties. Hence, the staining characteristics of cell tissues are best revealed when we employ an acid and basic stain, or what is known as double staining. This may be accomplished by two distinct methods: By using the stains (*a*) in conjunction, or (*b*) in suc

[1] MEDICAL RECORD, September 5, 1896.

cession. By the first method both stains are combined in the same solution. The second method requires two distinct solutions, the one following the other. In many regards I find the latter more desirable as well as more expedient.

In making a choice of dyes, two points should be considered: (*a*) There should be a wide contrast in color; and (*b*) the stains should act quickly. In these respects eosin is the ideal acid dye. And methylene blue, making a beautiful contrast, is one of our most reliable and durable basic dyes. I have observed that staining first in a slightly acidulated eosin solution, and counterstaining in a methylene-blue solution rendered alkaline, not only bring out the granules of the cell body more distinctly, by giving them a brighter tint, but increase the contrast between the oxyphile and basophile tissues of the cell. My rule, therefore, is to use an acid stain in an acid bath, and a basic stain in an alkaline bath. Hence I use the two stains prepared according to the following formulæ:

No. 1.

Spirituous eosin (Grübler's)	0.25 gm.
Alcohol absolute (Squibb's)	35 cc.
Distilled water	15 cc.
Aqueous solution of acetic acid (glacial) one per cent	10 minims.

Mix and allow to stand in an open vessel until, by evaporation, the quantity is reduced to 35 cc.

No. 2.

Methylene blue (Grübler's)	0.30 gm.
Alcohol absolute (Squibb's)	15 cc.
Distilled water	50 cc.
Caustic potash, C. P.	10 mgm.

Mix and allow to stand in a closed bottle for one month before using.

Precaution should be taken not to overstain in either of these solutions. The length of time which gives best results will depend upon the quality of the ingredients, the age of the solution, the amount of evaporation, and the quantity of acid and alkali added to these solutions. When the proportions are properly adjusted for each solution, excellent results can be secured by staining in the eosin fifteen seconds and counterstaining in the methylene blue ten seconds.

It is important to note that there are two varieties of eosin used in laboratory work: (*a*) aqueous and (*b*) spirituous.

(*a*) Aqueous eosin in aqueous solution is more or less removed from the tissues in the process of washing. I have observed that by adding alcohol to this solution, the eosin is more permanently fixed in the tissues, and also that it is not so readily removed by washing. In this form aqueous eosin stains granules very distinctly. But hæmoglobin is stained less rapidly and less deeply, while it is quickly decolorized and counterstained by the basic stain. On the other hand, the granules are not so readily decolorized, but remain beautiful and clearly defined.

(*b*) Spirituous eosin stains hæmoglobin quickly and deeply, and is not readily decolorized by the basic counterstain. It also stains the granules. But if overstaining is permitted, granules are so deeply and extensively stained that they seem to blend together, and their clearly defined contour is lost.

Hence I have found that aqueous eosin in a diluted alcoholic solution, very slighty acidulated, followed by the basic counterstain, is quite satisfactory in bringing out the granules and in showing the structures of nuclei. But overstaining in the basic counterstain should be avoided.

Spirituous eosin will show the red cells to a far better advantage, but it must be more strongly acidulated. Freshly prepared staining solutions are often unsatisfactory. Hence it is never safe to compare a recently prepared staining solution with one that has been in use for some time, unless they have first been tested on films of the same blood. Hence to secure comparative results I always (*a*) use the same strength of staining solution; (*b*) stain a uniform length of time; and (*c*) stain the shortest period that will give satisfactory results. When these points are observed and uniform results are not obtained, we may be quite certain that the failure depends upon a variation in the condition of the blood, and not upon a variation in the technique.

(*D*) Washing and mounting: After staining the films, they are washed in a normal salt solution (0.6-per-cent. aqueous solution of sodium chloride), by slowly passing the cover glass through the solution two or three times. Excessive washing should be avoided. The films are then dried between sheets of fresh blotting paper. After staining in the eosin and drying the film, the cover glass is quickly passed through an alcohol flame two or three times, the film surface uppermost. This is done to fix the eosin. Overheating should be avoided. After the staining is completed, the specimen is permanently mounted in Canada balsam. The mounted specimen is then ready for study.

(*E*) System of study: If a systematic method of classifying and recording the phenomena is not adopted, one becomes bewildered with the material before him. I find it a great help to observe the following points: (*a*) A mechanical stage should always be used; (*b*) also the same ocular and lens to secure uniform magnification: (*c*) a high power is very necessary; (*d*) good fields for observation should be selected; (*e*) we should avoid excessive or insufficient illumination, and should not study by artificial light; (*f*) and finally, a large number of observations should be made, and, if in doubt, a second film should be stained and studied before making deductions. If the delicate changes which take place in the process of cell disintegration are to be utilized for diagnostic purposes, too much precaution in these points cannot be taken.

Interpretation of Phenomena. — Before studying the appearance of cell tissues in disease, it is first necessary to fix in one's mind the shade or tint that a staining solution communicates to cell tissues in the normal state. This can be done only by long and persistent study. It then becomes comparatively easy to recognize abnormal conditions by a variation in the staining reaction of these tissues.

The Physiological Chemistry of Cells.—Believing that something more definite could be ascertained concerning the physiological chemistry of cell tissues and their nature and conditions, I recently undertook a series of staining experiments. I will briefly report the result. For each experiment six blood films were uniformly prepared and fixed. They were then stained, according to the methods to be described, mounted, numbered, and the technique recorded for each film. The following are the principles embraced in the experiments made:

First experiment: Films stained for varying periods of time in an acid stain (five seconds to five minutes).

Second experiment: Films stained for varying periods of time in a basic stain (five seconds to five minutes).

Third experiment: Films stained in an acid stain for a uniform period of time (fifteen seconds), followed by counterstaining in a basic stain for varying periods of time (five seconds to five minutes).

Fourth experiment: Films stained in a basic stain for varying periods of time (five seconds to five minutes), followed by counterstaining in an acid stain for a uniform period of time (fifteen seconds).

The films thus prepared revealed a great variety of

phenomena. At first these seemed perplexing, but subsequent study revealed laws by which the phenomena could be classified and interpreted.

Experiment I.—Effects of an acid stain on cell tissues:

(*a*) Red cells stained quickly and deeply. Hence hæmoglobin is distinctly oxyphile.

(*b*) All nuclei remain transparent. Hence they are not oxyphile.

(*c*) All cell bodies react more or less to the acid stain. Hence they are more or less oxyphile. The oxyphile tissue of the cell body appears as granules. This is probably hyaloplasm. The granules are observed over the entire cell body. Those appearing over the nucleus are not within the nucleus, but within that part of the cell body which intervenes between the nucleus and the observer.

That part of the cell body of young cells immediately external to the nucleus appears as a distinct ring or zone, which is strongly oxyphile. This zone fades or becomes less oxyphile toward the periphery of the cell. Hence, the contour of these cells is not clearly defined when stained by an acid stain alone. Therefore the oxyphile quality of the cell body of young cells is greatest near the nucleus, and decreases toward the periphery of the cell. If hyaloplasm is the oxyphile tissue of the cell body, it would then appear that hyaloplasm predominates in that portion of the cell body of young cells nearest the nucleus and decreases toward the periphery of the cell.

The cell body of phagocytes or mature leucocytes is not only more distinctly oxyphile, but is uniformly oxyphile throughout.

The cell body of eosinophiles is strongly oxyphile and uniform throughout.

Therefore it appears that as the cell develops and approaches maturity the oxyphile quality of the cell body increases. Hence the minimum proportion of hyaloplasm is found in young cells, and the maximum proportion is found in the older or mature cells. I have also observed that, as cell disintegration advances, the oxyphile quality of the cell body decreases.

Experiment II.—Effects of a basic stain on cell tissues:

(*a*) Red cells stain a light green, which becomes darker the longer the film remains in the staining fluid. Hence hæmoglobin is also basophile. From our first experiment it was found to be oxyphile. It is, therefore, both oxyphile and basophile, or an amphophile substance.

(*b*) Nuclei react to a basic stain. Hence they are distinctly basophile. They are never oxyphile. They may, however, remain almost indifferent to a basic stain. There is, then, a deficiency in chromatin, or the network of the nucleus, which bears the same relation to the nucleus as spongioplasm bears to the cell body.

Chromatin possesses the basophile quality of nuclei. In normal nuclei this is usually well marked in young cells, less marked in phagocytes, and still less marked in eosinophiles. Hence it seems that the basophile quality of nuclei decreases as they mature. The age of the cell is, therefore, an important consideration in estimating the staining quality of the nuclei. Achromatin is a neutrophile substance, and bears the same relation to the nucleus as hyaloplasm bears to the cell body.

(*c*) All cell bodies react more or less to the basic stain. Hence they are more or less basophile. The basophile tissue of the cell body appears as a network. This is probably spongioplasm. Transparent or opaque granules are observed over or within the basophile network of the cell body of all varieties of leucocytes. These granules, therefore, are not basophile. In young cells these granules are very indistinct, but become more distinct as the cell develops.

That part of the cell body of young cells immediately external to the nucleus often appears as a distinct transparent ring or zone, while the external portion of the cell body is well stained. Hence the contour of these cells is clearly defined when stained by a basic stain alone. Therefore the basophile quality of the cell body of young cells is least near the nucleus, and increases toward the periphery of the cell. If spongioplasm is the basophile tissue of the cell body, it would then appear that spongioplasm predominates in that portion of the cell body of young cells nearest the periphery of the cell and decreases toward the nucleus.

The cell body of phagocytes or mature cells is not only less distinctly basophile, but is uniformly so throughout.

The cell body of eosinophiles is very faintly basophile, and is uniformly so throughout.

Therefore, since the basophile quality of the cell body is well marked in young cells, less marked in phagocytes or mature cells, and still less marked in the eosinophiles, this experiment seems to justify the conclusion that the basophile quality of the cell body decreases as the cell develops and approaches maturity. Hence we conclude that the maximum proportion of spongioplasm is found in young cells and a minimum proportion is found in the older or more mature cells. According to this law, it appears that the eosinophile cell is a more highly differentiated cell, or a cell of higher development. On the other hand, I have observed when cell disintegration begins that the reverse of this law takes place, and the basophile quality of the disintegrating tissues increases. This is also observed in the disintegration of nuclei. As disintegration advances, the basophile quality of adult nuclei increases—as observed in nuclei of pus cells, which are very strongly basophile. Hence, if these observations have been correctly made, we may formulate two laws:

The law of development: As cell development progresses, the oxyphile tissues of the cell become more oxyphile, and the basophile tissues become less basophile.

The law of disintegration: As cell disintegration progresses, the oxyphile tissues of the cell become less oxyphile, and the basophile tissues become more basophile.

Experiment III.—Effects of staining with an acid stain and counterstaining with a basic stain:

(*a*) Red cells, after being stained in an acid stain, become a deeper oxyphile when exposed to a basic stain for a short time. When the counterstaining is prolonged, the oxyphile tint decreases and is finally lost, while the basophile tint increases until the cells present a deep purple tint. Hence hæmoglobin reacts to both an acid and a basic stain. It is, therefore, an amphophile substance, but shows a much stronger affinity for an acid than for a basic stain, and reacts to it more quickly.

(*b*) Nuclei present the same appearance as in our second experiment; that is, they appear distinctly basophile.

(*c*) The cell body of young cells appears distinctly basophile, with no evidence of an oxyphile tint. Hence, the faintly granular hyaloplasm of these cells, which took a distinctly oxyphile tint in our first experiment, is neutralized or decolorized from the action of the basic counterstain, and appears transparent, even when the counterstaining is for a short period of time. These transparent granules are set in a deep basophile background.

The cell body of phagocytes appears distinctly oxyphile. The oxyphile quality is confined to the gran-

ules, which seem to be set in a faintly basophile background. Hence both the spongioplasm and the hyaloplasm are stained, the one being faintly basophile and the other distinctly oxyphile. The effect of the basophile tint of the spongioplasm, with its contrast in color, tends to bring out the oxyphile tint of the granules even more distinctly.

Prolonged Counterstaining. — Prolonged counterstaining with the basic stain decreases the oxyphile tint of the granules of phagocytes until it is finally lost. But the granules at no time show a basophile tint. While, on the other hand, the basophile tint of spongioplasm gradually deepens up to a certain point, it then ceases to change, the ultimate tint varying according to the age or condition of the cell.

Hence it is evidence of disintegration if mature oxyphile tissues, stained in an acid stain, are quickly decolorized when counterstained in a basic stain, or when basophile tissues show an unusual susceptibility to the basic stain. Prolonged counterstaining has much less effect on the granules of the eosinophile cells, than upon the granules of phagocytes. Hence they retain their oxyphile tint much longer; at the same time the spongioplasm is less distinctly basophile.

Therefore it appears that the granules of eosinophile cells are strongly oxyphile, while the granules of phagocytes are oxyphile to a less degree, and the granules of young cells are faintly oxyphile. Hence it seems that all granules are distinctly oxyphile, but that their affinity for the acid stain increases as the cell develops and matures.

In a former paper I made the statement that granules are first basophile; that they become oxyphile; and, if the cell lives long enough, they again become basophile. The foregoing experiments are more recent, and demonstrate that my first interpretation was probably erroneous.

The granules of all leucocytes, even the youngest, according to our first experiment, are shown to be distinctly oxyphile. The second experiment shows that they are not basophile. And the third experiment demonstrates that in young cells granules are quickly decolorized by the basic counterstain, while in more mature cells they remain distinctly oxyphile, and by prolonging the basic counterstaining they finally lose their oxyphile tint. Hence, it seems that we may be justified in making the following deductions:

(*a*) Granules of the cell body of young cells are faintly oxyphile. (*b*) Their oxyphile quality increases as the cell develops. (*c*) When disintegration begins, the oxyphile quality decreases as the cell disintegrates. Further research is needed in this line before dogmatic statements should be made. It demonstrates one point, however; that uniform technique is absolutely essential if we wish accurate results.

A basic stain decolorizes oxyphile tissues very slowly. Hence it is an ideal counterstain.

Rule for basic counterstaining: The time allowed for a basic counterstain should be extended to the point that basophile tissues are well stained without decolorizing the mature oxyphile tissues.

Experiment IV.—Effects of staining with a basic stain and counterstaining with an acid stain:

(*a*) The basophile tint transmitted to the red cells by the basic stain (as shown in Experiment II.) is quickly decolorized by the acid counterstain, and the cells are quickly restained by the acid stain.

(*b*) The basophile tint of nuclei is also quickly decolorized, and they remain transparent. No amount of overstaining will give them an oxyphile tint.

(*c*) Spongioplasm of all cells is decolorized and remains transparent.

Deductions: An acid stain quickly decolorizes all basophile tissues. Hence it is not a satisfactory counterstain.

The Law of Analogy.—A study of the larger animal organism in health reveals the fact that some of the body fluids are acid, while others are alkaline. In disease these reactions are often altered or reversed. Hence, in the larger animal organism, when the functions are changed, the reactions of the secretions and excretions are altered. Or, inversely, when the reactions of the secretions and excretions are altered or reversed, it is evidence of perverted functions.

It will suffice to speak of only a few of the changes that occur in the chemical reaction of the body fluids in disease. The reaction of the saliva in health is distinctly alkaline. In certain diseases it may become acid. The normal reaction of the gastric juice is acid. This may increase until it becomes what is known as hyperacidity, or it may decrease until the acid reaction is absent. These extreme reactions are well-known points of the highest clinical significance. On the other hand, there can be but little doubt that equally as great changes take place in the chemical and staining reaction of cell tissues as are known to take place in the tissues and fluids of the larger organism.

The foregoing experiments have shown conclusively that the tissues and fluids of leucocytes have complex staining reactions, and that these reactions change with the growth and decay of the cells.

Histologically and chemically we find leucocytes to be extremely complex organisms. Between the nucleus and cell body there is a distinct dividing membrane. This membrane separates tissues of quite distinct staining reactions. On its inner surface it is in contact with two substances—the one neutrophile and the other basophile. On its outer surface it is in contact with two substances—the one distinctly oxyphile and the other basophile. The leucocyte itself is floating in the blood serum, which holds in solution the elements of nutrition, mingled with toxins and the complex products of cell and tissue disintegration. Through the membrane which separates the nucleus from the cell body, osmosis plays an important part in the vital process of the cell. Whatever nutrition the nucleus receives must pass through this membrane by the process of endosmosis. Whatever secretions or excretions are eliminated from the nucleus must pass through this membrane by the process of exosmosis. Hence there are delicate chemical processes taking place in the cell, equal to any going on in the larger body. Therefore it is evident that as we descend the scale of life, we find that the same laws are in force. The intricate chemical processes which are continually taking place in the larger organism are at work in its cells. Therefore, by analogy, if the staining reaction of any cell is observed to vary from that found in normal cells, we may conclude that there must be a fundamental cause within the cell. And since a change of appearance in tissues is preceded by a change in function, we may conclude that the cause of this unequal susceptibility to stain is a perverted function of the cell. This gives us another law of analogy between the larger animal organism and its leucocytes.

In conclusion, I wish to make a brief reference to the application of these observations to

The Diagnosis of Tuberculosis.—A careful study of one hundred tuberculous cases, including all stages of the disease, has shown conclusively that the law that brings about disintegration in a tuberculous patient brings about the same process at an earlier date in tuberculous leucocytes. In these cases I have found (*a*) marked disintegration going on in all varieties of leucocytes, and (*b*) a great decrease in the number of young cells. These conditions are evidence that the tissue-forming power of these cells is imperfect or defective. Hence, when these conditions exist

in cells, we may be absolutely certain that a similar condition already exists, or soon will exist in the larger organism. Therefore, from the condition of the various cell tissues observed in these cases, I feel justified in making the following

Deductions.—First, it is possible to estimate the degree of the tuberculous condition. Second, it is possible to estimate the degree of the recuperative power. Furthermore, the phenomena upon which the foregoing deductions are based are as follows: (1) The degree of the tuberculous condition may be estimated by (*a*) the amount of deviation from the normal percentage of each variety of cells; and by (*b*) the amount of cell disintegration in each variety. (2) The degree of the recuperative power may be estimated by (*a*) the staining power of the nuclei; (*b*) the percentage of leucocytes with no evidence of disintegration; (*c*) a relatively high percentage of young cells; (*d*) the abundance of well-stained granules of the phagocytes; and (*e*) the abundance of eosinophile cells rich in granules. I do not wish to give the impression that it is an easy task to interpret the phenomena presented in a specimen of tuberculous blood, and from them to reach a diagnosis. But it can be done. And when it is properly done, it furnishes a diagnosis based upon the fundamental principles of biology. Hence, from a study of the foregoing cases, I feel justified in claiming that the blood, aided by the microscope, together with a uniform and accurate technique, furnishes a means of making a positive diagnosis of the tuberculous condition early enough to allow of effective treatment.

INTUSSUSCEPTION: A REPORT OF TWO CASES WITH A PLEA FOR EARLY OPERATION.

By H. MEEK, M.D.,

FELLOW OF THE BRITISH GYNÆCOLOGICAL SOCIETY; GYNÆCOLOGIST TO THE LONDON GENERAL HOSPITAL AND VISITING GYNÆCOLOGIST TO THE LONDON INSANE ASYLUM, LONDON, CANADA.

The following two cases of intussusception are reported for two reasons: first, because it is the writer's belief that all cases of this kind, whether the termination be successful or fatal, should be reported in order that the profession may get correct statistics regarding this terribly fatal accident; second, because they illustrate the difference in results between early and late operation.

Case I.—April 21, 1896, I was asked by one of my confrères, Dr. Moore, to go with him about fifteen miles from London to assist in operating on a little patient suffering from intestinal obstruction, seen by him in consultation with Dr. Hughs, of Thorndale, The following history of the case was given me by the attending physician: Boy, aged eight years, only child, and always rather delicate; family history fairly good. While at school, April 17th, the little fellow was suddenly seized with colicky pains in the abdomen and vomiting. He came home from school, and the vomiting and pains continued during the night. Next morning, April 18th, there being no improvement, Dr. Hughs was called and on his arrival found the little patient in bed, still suffering from considerable abdominal pain and vomiting everything taken into the stomach. The temperature was normal and pulse 120. Abdominal examination revealed very little distention, but a tumor in the right iliac region tender on pressure and dull on percussion. The little fellow had been constipated and there had been no movement of the bowels since the onset of the symptoms. Dr. Hughs thought the condition might possibly be due to fæcal impaction and prescribed castor oil every two hours. The oil had no effect in moving the bowels or bringing away any gas. Next morning, April 19th, vomiting with regurgitation still continued, but the tumor was found to be smaller and less tender, although there had been no bowel movement and no gas had passed. The temperature still continued normal, or very little above normal; pulse, 130 and weak. An enema of soapsuds was tried without effect. Next day, April 20th, there being no improvement and symptoms of obstruction persisting, Dr. Moore of London was called and saw the patient in consultation with Dr. Hughs, at 7 P.M. the same evening. From the location of the tumor in the right iliac region, Dr. Moore thought the obstruction was probably due to disease of the vermiform appendix. It was decided to operate on the following morning, if the obstruction was not relieved in the mean time.

We arrived at the patient's home about 9 A.M., April 21st, between ninety and ninety-six hours following the onset of the symptoms, and found the condition of the little sufferer much the same as on the previous evening, except that there was more prostration from the continued vomiting and regurgitation. There had been no relief in the symptoms of obstruction, and, although vomiting had continued every day from the commencement of the trouble, there had been as yet no stercoraceous vomiting. The temperature was 99° F., and pulse between 130 and 140 and weak. Abdominal examination revealed less distention than one would have expected. A sausage-shaped tumor could be felt on the right side about midway between the iliac spine and the umbilicus, somewhat curved in its outline, dull on percussion, and slightly movable.

The diagnosis lay between intussusception and mechanical obstruction from bands in the region of the appendix. The points in favor of intussusception were: first, the sudden appearance and shape of the tumor shortly after the onset of the symptoms; second, the absence of marked distention of the abdomen; third, the absence of temperature rise, which is usual in cases of appendicitis.

Opposed to the diagnosis of intussusception was the fact that the characteristic bloody and mucous discharge from the rectum, upon which so much stress is laid in books, was absent in this case.

The patient was prepared for operation, and Dr. Moore made an oblique incision through the abdominal wall in the line of the tumor. On opening the peritoneum considerable yellowish serous fluid escaped and a tumor presented in the wound. On examination the tumor was found to be an intussusception of the ileum into itself, about six inches above the ileo-cæcal valve. The tumor was about three inches long; about three inches of unaffected ileum intervened between the ileo-cæcal valve and the apex of the tumor. The appendix vermifomis and cæcum were not involved. That portion of the ileum just above the intussusception ring was contracted, while above this portion the bowel was distended. The intestine below the tumor was somewhat contracted. An attempt was made to reduce the inverted bowel, but this could be only partially accomplished. The constricted portion had become softened and was torn through in one place. The affected portion was then exsected, about seven inches of the ileum being removed, and end-to-end anastomosis made with a Murphy button. A strip of iodoform gauze surrounding the part of the bowel operated on was brought out through the abdominal incision and the remaining part of the wound was closed by interrupted silkworm-gut sutures.

The little patient died of shock about one hour after the completion of the operation.

Case II.—Male infant, aged seven months, nursing, well developed, fat and plump. Previous to the

present illness he had not suffered from a single day's illness since birth.

About 8 A.M., September 29, 1896, he had a rather large stool, followed soon after by vomiting, restlessness, and crying, as if in pain, and later by bloody and mucous discharges from the anus, with straining and refusal to nurse. About noon of the same day the little patient was seen by Dr. A. T. Hobbs, resident gynæcologist of the London Insane Asylum, the baby being the only child of the chief male attendant in that institution.

The principal symptoms seen by Dr. Hobbs were bloody and mucous discharges from the anus, with straining and refusal to nurse; restlessness and crying, as if in pain; rapid pulse, normal temperature. The vomiting had ceased. A sedative was prescribed, and instructions were given to watch the effect and report the condition in three or four hours.

About 4 P.M. the father reported the condition of the baby not improved and was instructed to bring the patient to the operating-room of the asylum for examination. About 5 P.M., the infant was brought into the operating-room and was seen by Dr. Moore and myself in consultation with Superintendent Dr. Bucke and Dr. Hobbs.

When stripped and laid on the table the child presented an apathetic appearance, and regurgitated a considerable quantity of fluid from the stomach, and at the same time a considerable quantity of dark blood and mucus was discharged from the anus. Examination per rectum caused straining and more bloody discharge; otherwise the rectal examination was negative. The abdomen was soft and not distended. No tumor could be seen.

On palpation, however, a sausage-shaped mass with a slightly curved outline could be indistinctly felt above and to the left of the umbilicus. The mass was movable and slightly tender on pressure. A diagnosis of intussusception was made, and immediate operation was advised and was consented to by the parents. I was asked by Dr. Bucke to operate. The usual careful aseptic preparations were made. Chloroform was administered by Dr. H. A. Stevenson, assisted by Dr. Moore, Dr Hobbs, and Dr. Bucke. I made a median incision through the abdominal wall just below the umbilicus. The peritoneal cavity was opened and the incision was extended downward to the upper limit of the bladder, which came up on the abdominal wall half way to the umbilicus. The incision was also extended upward, to the left of and less than one inch above the umbilicus. The whole length of the abdominal wound was a little more than three inches. The abdominal wall was rather thick and fat. There was very little subperitoneal fat. The peritoneum was exceedingly thin. There was very little blood lost from the abdominal wound. The omentum presented in the wound was a thin curtain containing very little fat. The small intestines, not at all distended, were drawn out through the wound and wrapped in warm moist towels. The sausage-shaped mass, about six inches long and dark brown in color, was found to be caused by an intussusception of the ileo-colic variety (Treves), about ten or twelve inches of the ileum with its mesentery having slipped through the ileo-cæcal valve into the ascending and tranverse colon. The cæcum was also partially inverted. The appendix vermiformis was about three and one-half inches long, directed downward and inward, its tip dark red in color from hemorrhage due to intense congestion. Some adhesions had already formed at the point where the ileum had passed through the ileo-cæcal valve. The vessels in the mesentery of the portion of ileum involved were very much distended and dark in color.

On account of the adhesions and the swollen condition of the parts, reduction was less easily effected than one would have expected, considering that the operation was performed less than ten hours after the onset of the symptoms. After separating the adhesions I made steady pressure on the apex of the tumor, Dr. Moore at the same time making gentle traction on the ileum, and reduction was gradually accomplished. After reduction the discolored portion of bowel was carefully wrapped in hot gauze pads till the normal color was pretty well restored. The abdominal wound was then closed by interrupted silkworm-gut sutures, and the usual dressings were applied.

Before operation the little patient was suffering from considerable shock, evidenced by rapid and weak pulse and subnormal temperature. The pulse immediately after operation was 180 and weak, but fell gradually to about 140 next evening. The temperature rose to 103° F. during the night, but gradually dropped till it reached normal the next evening. There was considerable restlessness at times during the night and the day following the operation, but small doses of paregoric and choral had a quieting effect. There was a slight discharge of blood and mucus once after the operation, and a free movement of the bowels without any blood early next morning. The baby took the breast a few hours after the operation and regularly after this.

After the first twenty-four hours convalescence was practically uneventful. The sutures were removed from the abdominal wound on the eighth day. There was primary union. Up to the present time, February, 1897, now about five months since the operation, with the exception of slight constipation the infant has remained perfectly well.

The only other case of intussusception that I have seen was one operated on by Dr. Sands in Roosevelt Hospital, in the spring of 1886. An infant, male, at eight months, suffering from intussusception between forty-eight and seventy-two hours, was brought into the hospital, after inflation had been tried. Dr. Sands opened the abdomen and found an intussusception of the ileo-cæcal variety. He succeeded in reducing the bowel, but the infant died of shock eight hours after the operation.

Remarks.—Of the two cases reported occurring in my personal experience, Case I. belonged to the enteric variety, according to the classification in Treves' "System of Surgery," and was interesting from the fact that nothing whatever passed through the bowels, the characteristic bloody and mucous discharge from the anus being absent. If no purgative had been given in this case, and operation had been resorted to within the first forty-eight hours, or even seventy-two hours, I think there can be little doubt that the operation would have been successful. Case II. belonged to the ileo-colic variety, the most acute and rapidly fatal of all the varieties of intussusception (Treves' "System of Surgery"). This patient was operated on less than ten hours following the onset of the symptoms, and, as ascertained during the operation, none too soon. If the case had gone another ten hours, I do not think the operation could have saved the little patient's life.

The lesson learned by me from these cases has been, in intussusception operate early or not at all. Do not waste time in attempting to reduce by inflation with air or water, but follow the teachings of common sense, viz., under strict asepsis open the abdomen before adhesions have formed and reduce the inverted bowel.

Cancer of the Pharynx commences in sixty per cent. of the cases on the surface of the tonsils, and, as it causes little trouble in its early stages, is very apt to be overlooked.—WATSON CHEYNE.

Progress of Medical Science.

Perforating Ulcer of the Duodenum.—At a recent meeting of the Clinical Society of London, as reported in the *Medical Press*, Mr. Dunn related a case of this kind which terminated in recovery. The patient, while at work, felt a sudden pain in the epigastrium, attended with nausea and faintness. He was taken home, and subsequently brought to Guy's Hospital. The abdomen was distended and remarkably tympanitic. The normal hepatic dulness was absent. He was suffering great pain, and had an anxious expression of countenance. The abdomen was opened by a median incision above the umbilicus, which allowed of the escape of a quantity of gas and yellowish fluid. A small perforation was found in the anterior wall of the first part of the duodenum. This was closed with fine silk Lembert sutures, and the abdominal cavity flushed out with boiled water. The flushing process interfered with respiration, and so could not be thoroughly carried out; hence a Keith tube was put into the upper parts of the wound for the first twenty-four hours. The patient progressed well for ten days, when his pain returned and his temperature was raised. He became worse and the abdomen was opened a second time, on this occasion along the right costal margin, as it was thought that a collection of pus had formed between the liver and the diaphragm. Nothing was discovered except a few adhesions in this region, chiefly beyond the reach of the finger. An exploring needle passed through the eighth intercostal space was felt to traverse the abdomen and perforate these adhesions. A drop of pus was evacuated by this method. The wound was closed, the intention being to open and drain the abscess through the thorax at a later date. This was not, however, required, as the temperature fell immediately after the operation, and remained low till the sixth day, when the wound was found to be distended with pus. The removal of two sutures sufficed to evacuate this, after which the recovery was rapid. In discussing this case, Mr. Bland Sutton said that years ago he had come to the conclusion that duodenal ulcer was pathologically quite different from the gastric ulcer met with in chlorotic girls. Though the fact is not mentioned in text-books, these patients seemed always to have been persons addicted to spirit drinking, and were consequently bad subjects for surgical treatment. It occurred to him that the interference with respiration noted in the author's case when the abdomen was flushed with water might have been due to the temperature having been too low. In his opinion the temperature should not exceed 115° F., nor fall below 110° F., otherwise shock might be caused.

The Use of the Ice Bag in Cases of Heart Disease Due to Infection.—Dr. Gendre recommends the application of an ice bag to the præcordium in the cardiac complications of the several acute infectious diseases (*Therapeutic Gazette*). He states that an ice bag or small bladder containing cracked ice in small quantity should be applied, care being exercised that too much pressure is not produced. The ice bag should be separated from the skin by one or two layers of flannel; without this precaution cutaneous erythema will soon develop, and if the cold application is continued for a number of hours a superficial slough of the skin will occur. The patient should lie quietly upon his back, so as to avoid the necessity of fixing the bag against his chest; should he be restless, it must be applied by means of a bandage. Ordinarily the application should not be kept up for longer than three days. The effects which the author finds produced by the application of the ice bag in functional troubles of the heart—as, for example, those which are symptomatic of pericarditis, acute endocarditis, or the hyperpyrexia associated with any acute infection—are exceedingly interesting. In the first place, there is marked amelioration or disappearance of all painful symptoms. As a general rule, the patient finds at once that the application is comfortable and desires its further employment, and palpitation of the heart, which may have been exceedingly marked, is greatly improved. Thus it is frequent to find that the pulse on the first day will be 140 to 150: on the second, 120; on the third, 100; and on the fourth day of the application it may be only 80; the pulse is more forcible and no longer filiform and undulating, and any excess in cardiac action is quieted. The heart's action is more regular and its contractions are more energetic. The *bruit de galop*, or the reduplication of the heart-sounds with intermittence, usually disappears. Indeed, the effect of applying ice to the præcordium is, in the experience of Gendre, precisely analogous to the results of administering digitalis when this drug acts as a cardiac tonic. Not only does it produce a favorable influence upon these functional disturbances, but it also tends to relieve the inflammation of the pericardium or even of the heart muscle itself. After quoting several cases, the author gives as an example a case of endocarditis complicating acute rheumatism and associated with congestion of the left lung, the patient being a young girl.

Bacteriological Findings in Angina Lacunaris.—Dr. Edmund Meyer says that the secretion of the tonsil in a state of acute inflammation has been subjected to minute bacteriological research, and with the result that the streptococci pyogenes aureus and albus, the staphylococcus, and the pneumococcus are found to be associated with this disease, but without establishing with certainty the fact of any one of these micro-organisms being the actual cause. Animal experiments have given negative results. It is, indeed, possible, by rubbing streptococci into injured mucous membranes, to produce a fibrinous deposit; but an angina transmitted from man and running the course with which we are familiar has as yet never been produced experimentally in animals. The author found in fourteen cases staphylococci, usually staphylococcus aureus, not albus. He later explains that in these, which were his early cases, there was a defect in his technique by which streptococci were not found. In twenty-four cases staphylococci and streptococci were both present; in fifteen cases streptococcus pyogenes, in pure culture. Leaving out the first group of cases in which the technique was defective, he found streptococci present in overwhelming numbers in all, and he is in consequence convinced that it is the streptococcus which is the specific exciting cause of this disease, and that the staphylococcus in general is a rather innocent accompaniment of the streptococcus. Like his predecessor, Sendziac, in this line of research, and unlike Norris Wolfenden, he was unable to distinguish any difference in the clinical course of the disease in consequence of the presence of varying species of micro-organisms; that is to say, he could not distinguish clinically a streptococcus angina, or a staphylococcus angina, or a pneumococcus angina. In a few of his cases he found the diphtheria pseudo-bacillus of Hoffman present. This he finds impossible to distinguish, without guinea-pig injections, from a genuine Loeffler bacillcus. The Loeffler bacillus was present in only two cases, but in these the clinical course was identical with the others.—*Medicine.*

Dr. Holloway favors using nitrous-oxide gas, alone or mixed with a small quantity of ether vapor, as an anæsthetic in operations on the throat and nose.

PURULENT OPHTHALMIA OF THE NEWBORN.

OF the many dangers attending the newly born infant, ophthalmia neonatorum is the most to be dreaded. It is stated that one-third of all the blind in Europe become so from this cause. Its early recognition and unremitting treatment are of the utmost importance. In every obstetric case the physician should gently separate the lids of the infant, to assure himself definitely of the presence or absence of any eye discharge. Infection from the maternal passages manifests itself almost invariably by discharge on the third day, both eyes being affected, as a rule. Discharges appearing at a later period usually arise from soiled hands, towels, sponges: and only one eye may be primarily attacked. This conjunctivitis is never due to strong light or cold, as is popularly supposed, but has a definite specific origin.

Following a discussion of the Medical Society of Breslau concerning Credé's method of treating such cases with the aqueous solution of nitrate of silver (one grain to a drachm of distilled water), twelve thousand question blanks were sent out to physicians, with results that form an important contribution to the subject. These blanks were distributed throughout Germany, Austria, Switzerland, Belgium, and Holland. Reports were returned, giving statistics of eye disease in 302,971 new-born infants. Of these, 1,938 suffered from ophthalmia neonatorum. In Germany, sixty per cent. of eye disease was of this nature: in Austria, eighty per cent.; and in Switzerland, Belgium, and Holland together, ninety per cent. In all these cases the characteristic condition appeared within five days in seventy-six per cent. of the infants under observation. The discharge began after the fifth day in twenty-four per cent. In one-fourth of the entire number of cases, one eye was attacked primarily: in three-fourths, both were affected simultaneously. Seventy-one per cent. were completely cured. Nine per cent. discontinued treatment. Twenty per cent., or one-fifth of the 1,938 cases, retained permanent lesions of more or less severity.

This twenty per cent. with permanent ocular defects presented corneal scars, monocular or binocular: and one-half of these permanently damaged infants became totally blind. It was considered they were brought too late for cure—fifty per cent. of the blind babies were not seen until the ninth day of their disease, and twenty-five per cent. not until the fourteenth day.

Out of one hundred representative ophthalmologists consulted, seventy-nine were in favor of making Credé's method obligatory in routine obstetric practice. It is not difficult, does no harm, and may avert dreadful catastrophe. The eyes are first carefully washed with tepid water, and the lids thoroughly cleansed by means of absorbent cotton. A few drops of the two-per-cent. solution of nitrate of silver are then instilled into each eye. Materials used to wipe away the discharge must be burnt or otherwise destroyed. Twice daily some simple ointment should be applied to the margin of the lids, to prevent them from sticking together. In severe forms, when there is much swelling and a thick discharge gushing from between the lids, the foregoing nitrate-of-silver solution may be used every six hours. When the inflammatory action subsides, Muskett recommends that weak solutions of alum, sulphate of zinc, and perchloride of mercury be substituted. The astringent lotion may consist of from four to ten grains of alum or from one to two grains of sulphate of zinc to the ounce of water. Either of these may be used with freedom and safety. The mercury solution gives excellent results—one-half grain of the perchloride to six ounces of distilled water. Cold-water compresses give great relief after active treatment.

Should ulceration of the cornea ensue, in spite of active and earnest measures, the eserine treatment introduced by De Wecker may prevent perforation in even the worst cases. Four grains of eserine in one ounce of distilled water is the strength usually employed, though sometimes one grain to the ounce is better borne. A few drops are instilled into the eyes six times a day. This treatment is also of value in a form of corneal affection peculiar to infantile purulent ophthalmia, mentioned by Nettleship, in which the cornea becomes rapidly and almost entirely opaque. Whatever the degree of ulceration, marginal ulcers are not so serious as those centrally situated, and sight may be preserved. More than in any other disease, Dr. J. Lewis Smith urges the necessity of employing faithful and attentive nurses, who will carry out punctually the directions given. Two nurses are required, one for day and the other for night duty, since it is essential that the eye be frequently cleansed and the secretion washed away.

THE INTERESTS OF TRADE AND THE LIVES OF THE PEOPLE.

NO mention has been made in the news reports from the East of the occurrence of the plague in Calcutta. There has, however, been a widespread prevalence in that city of the disease called pestis minor, which some authorities regard as a mild form of true plague: others as a related affection, the relationship of the two being analogous to that of cow-pox and small-pox: while others again deny that there is any similarity in nature or symptoms between the two diseases, beyond

the fact that there is a swelling of certain glands in both. The Calcutta health authorities appear to incline to the latter view, and have published a statement that no cases of plague have occurred in that city. To this statement, however, the *Indian Medical Gazette* takes exception, not contradicting it specifically, but believing that there is more room for discussion than the medical board is willing to admit. The history of one fatal case is given, in which all the classical symptoms of plague were present—the high fever, the enlarged and painful glands, the petechiæ, and rapid death with the characteristic microorganism in the blood. The health authorities rejected the diagnosis of plague, contenting themselves with the statement "that it was clear that other reasons existed for the enlargement of the glands in the groin, which was reported to be one of the prominent features of the case."

The attitude of the medical board is easily understood from the commercial point of view; but, as our contemporary justly says, it is a shortsighted policy, and not likely to be in the best interests either of the public or of the mercantile community. A similar policy of concealment, in the supposed interests of trade, has had disastrous results in Bombay, as it almost always has everywhere. Bombay, says the *Gazette*, concealed its first cases, then minimized them, and now it is face to face with a severe epidemic, its trade is ruined, and by its flying population it is likely to spread the disease far and wide.

ILLEGAL PRACTITIONERS PROTECTED BY THE COURT.

The police-court magistrates of New York appear to possess unusual opportunities for defeating the attempts of those whose endeavor it is to secure the enforcement of the law. The immunity enjoyed by many who are practically breakers of the excise law is due in large measure to the action of the magistrates in releasing those who have been arrested on such a charge.

Quite recently Magistrate Cornell has espoused the cause of offenders against the medical-practice law as well. The particular case was that of a pharmacist, who has been doing business in Seventh Avenue for a number of years. One night a detective in the employ of an agent of the County Medical Society pretended that she was ill and that the child she had with her was also ill. She begged him to prescribe for both, and he sold her some medicine, which he recommended as likely to benefit her. A warrant was obtained on the detective's affidavit, and the prescribing druggist was arrested. He told the magistrate that he had prescribed at the earnest solicitation of the detective, who claimed to be a poor woman suffering from various ailments and whose child was also ill, and he added, with some show of reason: "If I had been a rich man and could put my prescriptions up in fine bottles and call them patent medicines, I could sell hundreds of bottles a day and no one would interfere with me; but I am poor and cannot make any great display, cannot fight a case like this as it should be fought, and I am singled out for an attack."

The magistrate promptly discharged the accused, asserting that he had broken no law and that he had done only what thousands of other druggists are doing every day. He advised the County Society, if it wanted to make a test case, to get evidence against some of the leading apothecaries, who have money and can make a fight that will settle the question of the druggist's right to do the work of the physician.

On the same day another man, not a druggist, was arraigned before the same magistrate for practising medicine without being duly registered. He pleaded not guilty, but, with the inconsistency of a great mind, the magistrate held him for trial.

We think there may have been an apparent hardship in proceeding against the accused druggist, and one's sympathies are naturally aroused in favor of one who is entrapped into wrong doing by a detective. And we believe there are other and better ways for catching law breakers than by tempting them to break the law. But we do not see that it justifies a judge, whose duty it is to uphold the laws and punish wrong doers, in discharging a man accused of a crime when there was no doubt that the illegal act was committed.

A FATAL OMISSION IN THE CODE OF ETHICS.

Dr. Atkinson, the secretary of the American Medical Association, replying to an anxious inquirer, who asks whether it is right for specialists to divide fees with those who send them patients, says that "the offering or giving any portion of a fee to one who procures cases for another is the worst possible means of obtaining practice. Both parties are equally guilty of a breach of honorable dealing. Such conduct is on a par with the acceptance by a physician of a percentage from an apothecary to whom he directs his prescriptions to be taken. So patent did this appear to those who framed the code of ethics that they did not deem it necessary to insert any clause in regard to it."

By all means let this omission be repaired at the Philadelphia meeting. A bill is before the Kansas legislature to enact the ten commandments into law, with severe penalties for any breach of them; and certainly the morals of the members of the American Medical Association ought to be safeguarded as carefully as those of the citizens of Kansas. For the sake of brevity, perhaps the golden rule would answer.

An Active Old Man.—The Dublin correspondent of *The Lancet* writes that at an athletic contest held recently at Freemont, County Cork, a man named James Loder, aged eighty-two years, covered thirty-three feet in three standing jumps. Several young men failed to come within three feet of this distance. Old Loder weighs only one hundred and twelve pounds, and is remarkably vigorous. It is asserted his father lived to the age of one hundred and ten years.

News of the Week.

Death by Hanging without Strangulation.—The Berlin correspondent of the *Medical Press* relates a case, reported by Dr. Reineboth, of Halle, of a man who hanged himself after a tracheotomy had been performed. In doing so he passed the cord round his neck above the tracheal cannula, so that respiration could still go on unimpeded. Death appeared to have taken place rapidly. The case shows that death by hanging is not brought about by preventing respiration, but by pressure on the large vessels. The position of the body also was such that with continued consciousness the man would have been able to get on his feet again. It appears from this that loss of consciousness was as rapid as in ordinary hanging. The autopsy showed anæmia of the cerebrum, extreme fulness of the vessels of the base, slighter fulness of those of the pia mater, hyperæmia of the pons and medulla. Death by hanging without strangulation is not unknown in literature, but this case is probably unique.

The Tri-State Medical Society.—The fifth annual meeting of the Tri-State Medical Society of Iowa, Illinois, and Missouri, will meet in St. Louis, April 6, 7, and 8, 1897. Dr. Joseph Price, of Philadelphia, will hold the surgical clinic; Dr. James T. Whittaker, of Cincinnati, the medical clinic; and Dr. Dudley Reynolds the ophthalmic clinic.

A Proposal to Move the Morgue.—The health board has asked the dock commissioners to allow the Morgue to be moved from its present location, in the grounds of Bellevue Hospital, to the end of the pier at the foot of East Twenty-sixth Street.

Dr. J. Mount Bleyer, of New York, has been appointed co-referee in the discussion on *x*-rays at the Moscow congress.

The London Water Supply.—A commission appointed by *The Lancet* has been making an investigation of the water supply of London, and from its report we learn that the town is supplied with water partly by deep wells, but chiefly by eight water companies. A comparatively small amount of water only is derived from the wells, and the quantity of water which can be obtained from them has lessened year by year, for the level of the underground water has sunk. It is possible that a few surface wells remain. Some movable pumps are still used by builders in the Chelsea district, but it is unlikely that much of the water is used for drinking. Of public pumps in London, one of the last to go was the historic one of Aldgate, but for years before its removal it had been supplied by water laid on from the mains of the New River Company, in accordance with the directions of the medical officer of health for the city of London, who, finding that the local water was extremely impure, and knowing that the inhabitants would not tamely submit (if they knew it) to any alteration in their cherished water supply, by a pious fraud allowed them for years to pump water from the New River supply.

Obituary Notes.—Dr. Ernst Ilgen, of Brooklyn, died at his home in that city, on March 4th, in his eighty-third year. He was a graduate of the University of Munich, and came to this country in 1851. He practised for a long time in this city, but removed to Brooklyn some years ago.—Dr. Robert Todd Reynolds died in Chicago on February 28th, in the eighty-sixth year of his age. He was a graduate of McGill University in 1836, and at the time of his death was reputed to be the oldest living graduate of that school. He practised in Canada for over fifty years, retiring from active work five years ago.—Dr. Lewis Hallock died in this city on March 3d, in his ninety-third year. He was born in New York, and began the study of medicine at Southold with a relative, Dr. Elisha Hallock; after one year he entered the office of Dr. John W. Francis, professor of obstetrics in the College of Physicians and Surgeons in this city, and was graduated from that college in 1826. After practising for fifteen years he became interested in homœopathic methods, and finally joined that school, being the twelfth member of the Homœopathic Association. In 1844 he with others founded the American Institute of Homœopathy.—Mr. William Wallace Blake, the superintendent of the outdoor poor for many years, is dead. He was a man of rough exterior, but one who always dealt most kindly with those who applied to him for relief and whom he did not know to be impostors.—Dr. Henry M. Black died at Strasburg, Pa., on February 28th, at the age of forty-five years. He was graduated from Jefferson Medical College in 1875.—Dr. Joseph F. Gallagher died on March 3d at Freeland, Pa., at the age of twenty-five years. He was graduated from Jefferson Medical College in 1891.—Dr. George A. Sterling, for many years a leading physician of Sag Harbor and Southampton, Long Island, died in Oakland, Cal., March 8th. He was a native of Sharon, Conn., and a graduate of Bellevue Hospital Medical College. Last November he started for the Sandwich Islands, to regain his health. When he reached San Francisco he was too ill to proceed. He was about fifty-five years old. He leaves a widow, three sons, and six daughters.

Cigarette Laws in Chicago.—The city council of Chicago, by a unanimous vote, has passed an ordinance requiring every dealer in cigarettes to pay an annual license of $100 to the city treasury. The law passed says that cigarettes cannot be sold within two hundred feet of a school house. All sold by licensed dealers must have been inspected by the commissioner of health and received his approval as to their purity. No cigarette can be sold which contains opium, morphine, or other poisonous matter. Any violation of these provisions of an ordinance passed by the council subjects the dealer to a fine of from $50 to $200 for each offence, and $25 for each day of the violation of the law.

Smoking at Society Meetings.—The question whether smoking should be permitted members during the meeting has been discussed by several of the London medical societies. In the Harveian Society re

cently the proposition was unanimously voted down after discussion, in the course of which the president said that, while sympathizing with the wishes of the smokers, it was also necessary to look at the question from a much broader point of view. The society was one of the oldest medical societies in London, and the members ought to be very careful not to introduce any innovation which would be detrimental to it or other societies which might follow its example. Dr. Norman Kerr said that though he did not smoke now, he had been a smoker for a long series of years, and had derived much enjoyment therefrom: but he had always looked upon it as a matter of fairness and honor never to enjoy the weed in the presence of those who neither approved of nor relished the use of tobacco. There were medical men whom smoking by others in a room made uncomfortable, and he thought it unjust to deprive such members of the full enjoyment and profit of attendance at meetings, which was a right inherent in membership.

The Tennessee Centennial.—It is hoped by the managers of the exposition to be held in Nashville this spring that everything will be completed for its opening at the appointed time. Work has been begun on the building for hygiene, medicine and sanitary appliances, and education. This will be a large and handsome building, with twenty thousand feet of floor space, one-half of which will be devoted to medicine, and will occupy a position between the auditorium, the administration building, and the United States government building. Dr. J. D. Plunket, chief of the department of hygiene, medicine, and sanitary appliances, has the various sections of his department already well organized. These sections are as follows: Section A.—Hygiene and sanitary appliances: Dr. E. B. Sangree, chairman of the organization committee. Section B.—Medical history (Tennessee especially), literature, books, journals, pamphlets, statistics, etc.: Dr. Deering J. Roberts, chairman. Section C.—Surgical and medical instruments, appliances, dressings, etc.: Dr. Charles S. Briggs, chairman. Section D.—Drugs, pharmacy, pharmacology, and dietetics intended for the sick: J. Criddle Wharton, Ph.D., chairman. Section E.—Dental apparatus, instruments, and prosthesis: J. Y. Crawford, M.D., D.D.S., chairman. Section F.—Hospitals, vehicles, and appliances for transporting sick and wounded: Dr. John R. Buist, chairman. Section G.—Physical development and condition: Dr. Joseph T. Gwathmey, chairman.

Dr. J. Chalmers Da Costa has been appointed clinical professor of surgery in the Jefferson Medical College of Philadelphia. Dr. Da Costa has been connected with the college for many years, and has recently been demonstrator of surgery and chief of the out-patient department.

The Plague.—It is reported that the plague in Bombay is declining slowly, whether from lack of material, since most of those who are susceptible to its attack have left the city, or from other causes, we do not know. The official report, issued by the health authorities of the city, gives the total number of cases, from the time when the disease was declared epidemic up to March 4th, as 8,383, and the number of deaths as 6,979. But probably, as the *Times of India* argues, many cases have not been reported, and many deaths which were really of the plague have been ascribed to other causes. This assumption is based upon the enormously increased death rate from other diseases which the official statistics show.

Pneumonia is reported to be unusually prevalent in New York at the present time. The deaths from this disease have averaged lately about twenty a day.

Medical Service in the British Army has become very unpopular, as a result of the unjust discrimination against the medical officers by the military authorities. At a recent examination for thirty-five vacancies, only thirty-one candidates appeared, though the rule forbidding a man from trying after having failed twice was suspended.

The Competition for Accident Cases has become so active among the ambulance surgeons that it has been found necessary to establish rules of precedence at fires. These rules provide that whenever a general ambulance call is made for a disaster, explosion, collapse of building, or a fire of unusual proportion, the surgeon first reaching an injured person shall be considered in charge of the case; if surgeons from different hospitals reach the case at the same time, the one from the nearest hospital shall take it. Any differences between surgeons at a fire shall be settled by the highest officer of the fire department present, and should any surgeon fail to comply with the rule that officer shall report him to the charities department.

Lord Kinnear Nolens Volens.—The editor of the *Journal of the American Medical Association* apparently refuses to admit Lord Lister's right to be called by the name of his own choosing, for he persists in speaking of him as Lord Kinnear, despite the amused protests of the British medical press against this blunder of a London news agency.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending March 6, 1897: February 27th.—Assistant Surgeon M. S. Elliott detached from instruction at the naval laboratory, New York, and ordered to the United States steamship *Columbia*.

The Texas Legislature is honored by the presence of six medical members. We shall look for the enactment of some beneficent medical laws in that great State.

The First Fine for Spitting in the Cars was imposed on Tuesday last upon a man in this city who violated the health ordinance. The amount of fine was $5. The man pleaded ignorance of the law, but without avail. A few such lessons to passengers in the elevated and other cars, particularly of the east side, would prove to be wholesome reminders of ordinary decency.

"The Railway Surgeon" announces that it will publish a daily edition during the sessions of the National Association of Railway Surgeons, to be held in Chicago, May 4, 5, and 6, 1897.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending February 27, 1897: February 20th.—Passed Assistant Surgeon G. T. Smith detached from the *Adams*, on reporting of his relief about March 2d, ordered home, and granted two months' leave; Passed Assistant Surgeon L. H. Stone detached from the naval hospital, New York, March 15th, and ordered to the *Adams*. February 23d.—Surgeon G. P. Bradley detached from the *Indiana*, March 3d, ordered home, and placed on waiting orders; Surgeon N. McP. Ferebee ordered to the *Indiana*, March 3d; Passed Assistant Surgeon W. F. Arnold ordered as a member of the medical examining board, League Island navy yard; Passed Assistant Surgeon L. W. Atlee detached as member of the medical examining board, League Island navy yard.

A Water Famine and Disease in Oaxaca.—A dispatch to the daily papers from Puebla, Mexico, says that the city of Oaxaca has a water famine, which is causing great suffering among the people of that place. All the fountains have gone dry and the water supply of the city is exhausted. As a result of these conditions, it is said, a peculiar disease has broken out among the poorer classes, which is alarming in its fatality. The patient is first stricken with vomiting of blood, which soon results in death.

Restrictions on the Sale of Alcohol.—A bill has been introduced into the Missouri legislature imposing a tax of from $300 to $400 a year upon all pharmacists selling any alcohol or intoxicating liquors in quantity less than four gallons. And, in addition to taking out a license and paying this heavy tax, the bill forbids the druggist to sell or give away any alcoholic liquor, other than wine for sacramental purposes and alcohol for art, mechanical, or scientific uses, "except on a written prescription, dated and signed, first had and obtained from some regularly registered and practising physician, and then only when such physician shall state in such prescription the name of the person for whom the same is prescribed, and that such intoxicating liquor is prescribed as a necessary remedy." We do not know whether the courts would decide that tinctures are "alcohol or intoxicating liquors of any kind," but, even were they excluded, the law would interfere most unjustly with the legitimate business of the druggist in the compounding of prescriptions.

Dr. William Osler, of Baltimore, delivered a lecture upon "The Influence of Louis upon American Medicine," in the auditorium of Houston Hall of the University of Pennsylvania, on February 17th, under the auspices of the State Medical Society.

Deaths from Illuminating Gas.—According to the annual report of the Massachusetts gas and electric light commissioners, recently submitted to the legislature, fifty-one persons were killed by escaping gas during the year, and one hundred and eighteen were injured. The board recommends greater care on the part of the companies, by thorough inspection of pipes and fixtures. In Philadelphia, during the same period, thirty-three persons died from the effects of illuminating gas, inhaled accidentally or with suicidal intent.

Scientific Congresses at Brussels.—Several hygienic and other congresses to discuss subjects of medical interest will be held in connection with the International Exposition of Brussels. Among these will be the following: A medico-legal congress, an anti-alcoholic congress, a congress for the furtherance of public morality, one on the dwellings of the poor, one on public hygiene, one on the hygiene of transportation, and possibly others.

Special Hospital for the Treatment of Digestive Disorders.—A new hospital for the treatment of diseases of the digestive tract has been organized in Philadelphia, and promises to be soon in active operation. Already $60,000 have been collected for the purpose, a site has been selected, and a board of managers and a medical staff agreed upon. The new institution is to be known as the American Hospital for Diseases of the Stomach.

Vienna Sanitary Congress.—It is announced that England has put a stop to the pilgrimages to Mecca on account of the bubonic plague. Dr. Cleghorn, who has arrived from Bombay, reports that the disease in his opinion is neither contagious nor infectious. The danger of introducing the plague into Europe will be greatly decreased by the action of England, coupled with that already taken by Russia and Austria.

"The Laryngoscope," published in St. Louis, has, we learn from the *Medical Review*, been selected as the official organ, for the year 1897, of the laryngological section of the New York Academy of Medicine.

British Medical Men.—According to the Medical Register for 1897, the number of registered practitioners with British qualifications is 34,478. The number in the Register of last year is 33,601, or an increase of 877. The particulars of this huge total are as follows: New registrations—England, 780; Scotland, 477; Ireland, 128; restorations to the Register, 52; total, 1,437. From this must be deducted for removals by death, 532; under section 14, 25; under penal section, 3; total, 560. The actual number on the Register is affected by the removals chiefly under section 14, which is a mere postal matter, and subject to variation according to circumstances or the action of the council. Though the number on the Register grows from the excess of new registrations over the number of deaths, it does not appear that the number of new registrations is increasing. For the last three years the numbers are, respectively, 1,579, 1,426, and 1,385.

The Weather Bureau in Its Relation to Medical Climatology.—The following resolutions were adopted by the Medical Society of Bernalillo County, New Mexico, at a meeting held January 15, 1897: *Whereas*, This society is impressed with a sense of

the supreme value of the methods and work of the Weather Bureau of the United States, in their relation to the science of Medical Climatology, as illustrated in the series of statistical tables published in Volume I., Annual Report for 1885, of the Signal Service (now Weather Bureau); said tables embracing all the data bearing upon nearly every meteorological feature necessary to a complete determination of the climate of many points scattered over the whole of the United States, so far as these data had accumulated up to the date of that Report, and *Whereas*, The value of these tables would be greatly enhanced by working into them the data accumulated in the course of the eleven years which have elapsed since 1885, and a volume of immense value to the medical profession might be produced by appending to these tables, brought up to date, some account of the topography, geological formation, natural drainage, nature and source of water supply, vicinity of mineral springs, etc., etc., at each station where observations are taken; therefore *Be it Resolved*, By the Medical Society of Bernalillo County, New Mexico, that the Chief of the Weather Bureau of the United States be respectfully requested to take this matter into consideration; that the American Climatological Association be requested to co-operate with the Weather Bureau through a committee appointed for that purpose, if mutually agreeable; that copies of these resolutions be transmitted to the Chief of the Weather Bureau, to the Surgeons-General of the Army, Navy, and Marine Hospital Service, to at least three of the principal medical journals of the United States, to the American Public Health Association and the American Medical Association, and to every State Medical Association in the United States, and their co-operation invited.

Regulating the Medical-Charity Evil.—The Medical Asssociation of the District of Columbia, at a meeting held February 16, 1897, adopted some resolutions looking to the correction of some of the dispensary and hospital abuses there, as elsewhere, existent or potential. The recommendations of the society were in substance as follows: That every institution for medical charity shall require from every applicant for relief in a hospital or dispensary a written certificate to be obtained from physicians to the poor, the board of associated charities, or any registered physician. Emergency cases are to be excepted from the operation of this rule. That any sick and injured person found upon the streets or elsewhere, who requires immediate treatment, shall be carried to the Emergency Hospital, or to the nearest hospital having an emergency service, or to his home, if so directed by the patient or his friends. That if carried to a hospital such patients shall not be detained longer than the necessity of the case imperatively demands, but shall be discharged from the service and sent to his home or to some public hospital as he may elect. That members of the association shall be entitled to the privilege of attending private patients occupying private rooms in any of the public hospitals of this city. That the members of the medical staffs of hospitals when attending medical or surgical cases in private pay rooms shall insist upon proper payment for their services except in the case of such patients who are clearly unable to pay for same. That whenever the medical staff or a majority thereof of a hospital or dispensary resigns, or whenever one or more members of the medical staff of a hospital or dispensary are dismissed, and when after due investigation, the association finds that such resignation was for just and sufficient cause, or that such dismissal was without just and sufficient cause, it shall be forbidden for any member of this association to fill the vacancy or vacancies created thereby.

Dr. A. Von Grimm has been appointed attending physician to St. Mark's Hospital in this city.

Section of Dentistry of the Twelfth International Medical Congress in Moscow.—The following is a preliminary programme of the work of this section: 1. What kind of general and special learning is desirable for the persons who are to occupy themselves with dentistry? by Dr. Julius Scheff, of Vienna; 2. The hygiene of the cavity of the mouth and of the teeth; 3. General and local anæsthetics for tooth extraction, by Dr. V. Richardson, of London; 4. Kataphoresis in dentistry; 5. The essence and treatment of pyorrhœa alveolaris, by Dr. József Arkövy, of Budapest; 6. The treatment and filling of pulpless teeth; and 7. Crown and bridgework from the hygienic and technical point of view, by Dr. Morgenstern, of Baden-Baden. In accordance with the rules of the congress, these papers, the titles having been first received, will have precedence over others. This does not, of course, exclude communications upon other subjects, but such communications can be read only if time permits. It is very important that an abstract of any paper that is to be read be forwarded before May 1, 1897. The chairman of the section is Dr. F. Rein, Little Dmitrowka Street, h. Scheschkow, Moscow.

Pathological Society of Philadelphia.—A stated meeting of the Pathological Society of Philadelphia was held on February 11th. Dr. Joseph Sailer exhibited an endothelioma of the left superior pulmonary vein, and also a brain presenting symmetrical multilocular subarachnoid cysts in the temporal region. Dr. H. L. Williams exhibited a ruptured tubal gestation sac, together with the fœtus. Dr. H. A. Hare exhibited a specimen of senile gangrene involving the foot. Dr. A. E. Taylor read a paper entitled "A Contribution to the Pathology of Albumosuria." Dr. A. H. Stewart detailed the report of a case of cystinuria, and exhibited specimens of cystin crystals. Dr. D. J. McCarthy exhibited a heart presenting stenosis of both auriculo-ventricular orifices, and also a urethral bougie extemporized from a kitchen poker. Dr. Judson Daland showed from one case a brain presenting the remains of an old hemorrhage into the basal ganglia, an old and a recent cardiac thrombus, granular kidneys, and aneurismal dilatation of the right vertebral artery. Dr. Joseph Sailer exhibited a liver presenting unusual fissuration. Dr. William S. Carter exhibited for Dr. M. H. Fussell lungs, heart, kidney, and uterus from a case of hemorrhagic purpura.

The Fortunes of Medical Men.—Among the wills of members of the medical profession proved during 1896, that of Dr. Patrick Fraser, with his £420,000 of personalty, lifts its head, "like some tall Alp," dwarfing the others into insignificance. Next, but *longo intervallo*, come Sir John Erichsen, with a little less than £90,000, and Sir George Humphry, with a trifle under £80,000. Dr. Samuel Holdsworth, of Wakefield, who died at the age of eighty-three, left some £53,000, and Mr. William Statter, of the same town, some £40,000. Dr. George Harley and Sir William Moore come close together with about £25,000 each, an amount which Sir George Johnson and Sir Russell Reynolds scarcely make up between them. —*The Practitioner*.

Heroic and Hygienic Young Ladies.—A London contemporary notes, with approving comment, that "a number of unmarried women of New York have formed a society for the prevention of hereditary diseases. They have registered a solemn vow not to marry any man whose family is tainted with consumption, insanity, alcoholism, or other heritable disease." This is probably, or ought to be, united in sororal bonds with that noble band of maidens which another of our envious British contemporaries says has been formed somewhere out in Cook County, with the equally laudable, though somewhat more selfish, object of discouraging kissing in the dark.

Punished for Defending a Clerical Quack.—The Paris correspondent of *The Lancet* says that Dr. Guermonprez, surgeon to the hospital at Lille and professor at the Catholic University at that town and a well-known gynecologist, has been boycotted by the profession for having accepted the medical certificates of a priest who practises medicine illegally at Sens and who has been many times convicted for his misdemeanor. Dr. Guermonprez, whose religious convictions are responsible for his attitude, attempted to lighten the rigors of the law for the priest, with the result that he has been expelled from the Surgical Society of Lille.

Serum Diagnosis by the Philadelphia Board of Health.—Upon the suggestion of Dr. A. C. Abbott, director of the bacteriological laboratory of the Philadelphia board of health, examinations of specimens of dried blood from suspected cases of typhoid fever will be made and reports furnished to the physician in charge.

Bellevue College.—The officers of Bellevue Medical College have decided to replace the college building, which stood in Bellevue Hospital grounds and which was recently destroyed by fire, by a more modern and substantial structure, which will be erected on the south side of East Twenty-sixth Street, next to the Carnegie Laboratory, opposite the main entrance to the hospital. The old college building was erected by the city, and the upper part of it was given over to class and lecture rooms, while the free dispensary for the out-door poor was maintained on the Twenty-sixth Street side of the lower floor. Even before the fire there was some talk of a removal of the college, as the commissioners of charities wished for hospital purposes the ground on which the building stood. The new structure will have a frontage of one hundred feet on First Avenue and one hundred and fifty feet on Twenty-sixth Street. It will connect directly with the laboratory building. It is thought that the new building will be ready for occupancy on September 1st.

Deaths from Famine.—Dispatches from Delhi, India, say that in Sirsa, where there is more suffering from the famine than in any other part of the Southern Punjab, the death rate has reached twenty-three per cent. of the population, forty thousand persons having died.

Shakespeare on Appendicitis.—An esteemed correspondent, who says that, as the good Hebrew believes everything can be found in the Talmud, so a good Anglo-Saxon thinks that everything is in Shakespeare, calls our attention to a reference to the appendix in the "Taming of the Shrew." He thinks it is particularly appropriate, although he would cast no reflection on any particular hospital. The quotation reads: "My master hath appointed me to go to Saint Luke's, to bid the priest be ready to come against you come with your appendix." Later this same appendix is ranked among the "froward and unable worms." But here Shakespeare's prescience fails him for once, for he makes *Lucentio* return from Saint Luke's with his "appendix" attached to him more securely than before. Perhaps this remarkable escape may be due to the fact that, although "Curtis" had been about, he had made his exit before the "appendix" was brought in.

The "Wisconsin Eclectic Medical College," which claims to hold a charter from the State of Wisconsin but which does business in Chicago, has reduced the price of its diplomas from $35 to $20, or we know not how much lower. The sole requisite for graduation is to "send us your name in full exactly as desired in diploma, and we will on receipt of the same send on the diploma per express C.O.D., you having the right of examination before making payment of the fees." The diploma is printed on artificial parchment, but upon payment of $2 in advance the candidate can have a "real sheepskin." It is strange that the physicians of Chicago can or will do nothing to remove this stigma from themselves and their city. One of our esteemed contemporaries published there punctuates its editorial page with "Let Us Have a Department of Public Health!" We would suggest, as a substitute for this, "Let Us Have No Diploma Mills in the Capital City of the American Medical Association!"

Dr. Alonzo Blauvelt, chief inspector of the bureau of contagious diseases, has been appointed chief medical school inspector of New York, under the system recently adopted by the health board for the examination of children attending the schools. The one hundred and fifty medical examiners provided for under the new system will be appointed by the health board as soon as the civil-service commission furnishes the required list of applicants.

Reviews and Notices.

A Guide to the Clinical Examination of the Blood for Diagnostic Purposes. By Richard C. Cabot, M.D. With colored plates and engravings. New York: William Wood and Company. 1897.

The great importance of the study of the blood has always been sufficiently recognized, but only of recent years has the practical value of these researches come to light. Behring's (serum) antitoxin treatment of diphtheria, Vidal's blood test in the diagnosis of typhoid fever are well-known to every practitioner and prove the above statement. A work on the condition of the blood in health and disease is, therefore, a very welcome addition to American medical literature. Cabot is an expert on blood, and he has treated this subject from the practical standpoint and from his own great experience.

As indicating the great clearness with which this masterful book is written a few sentences which treat on the blood in pernicious anæmia are quoted:

"The drop as it emerges from the puncture is often excessively pale and watery, but not more so than may occasionally be seen in secondary anæmia or chlorosis. Sometimes it is not nearly so pale as in other cases with equally low counts, a fact which may be due to the increased color index sometimes present. In one case I have seen the blood as red as normal.

"Another appearance which I have frequently observed in this and other anæmias is an uneven, streaked color in the drop, as if the cells were unequally divided in the plasma.

"As striking as the color of the drop is its great fluidity; the rapidity with which it slips off the ear or finger often makes it difficult to suck it up in time. It is usually very slow in coagulating.

"The fresh specimen in most cases shows no rouleaux formation, a diminution in blood plates and fibrin, and usually great variations in the size and shape of the corpuscles. Not infrequently the deformed corpuscle shows active pseudo-amœboid motions of its projecting points or of the cell as a whole. The great lack both of red and white cells is noticeable even in the slide and cover-glass specimens."

Traité de Thérapeutique et de Matière Médicale. Par Victor Aud'houi, Médecin de l'Hôtel Dieu de Paris. Pp. 1,200. Paris: G. Steinheil. 1897.

This work contains a scientific classification of the properties of medicinal agents which have actually been determined. It presents a valuable book for the medical student as well as for the practitioner.

Traité de Médecine et de Thérapeutique. Par Brouardel, Gilbert, et Girode. T. I. Maladies microbiennes. Paris: Baillière et fils. 1895.

The true name for this most excellent work should be "Modern Medicine," for it treats on all subjects from the latest point of view. The etiological factors are here given more consideration than in any previous works. This is already shown in the new terms some of the diseases have received; thus, "pneumococcie" instead of "pneumonia," "streptococcie" instead of "pyæmia," etc. The new work will be read with interest and profit by every practitioner of medicine.

Diseases of the Stomach. A Text-Book for Practitioners and Students. By Max Einhorn, M.D., Instructor in Clinical Medicine at the New York Post-Graduate Medical School and Hospital; Visiting Physician to the German Dispensary. New York: William Wood and Company. 1896.

"Diseases of the Stomach" as a specialty by itself is a result of the modern-day division of the field of investigation and therapeutic effort.

It is only some twenty years ago that Leube first made use of the stomach pump for diagnostic purposes, and we may regard strictly scientific investigation and treatment of stomach diseases as dating almost from that period. The writings of Dr. Einhorn have made his name one of those most closely identified with stomach disorders. His present work, which presents the acquisitions of late years in matters of diet and local, general, and surgical treatment of the stomach, will therefore be read with interest.

Much of the ground has been covered in a series of articles contributed by the writer to the "Twentieth Century Practice of Medicine," but in the present monograph the whole subject has been approached from the more practical side, and many details essential to an exhaustive scientific presentation of the subject have been replaced by matters of diet, and management of cases more in keeping with the requirements of the man who consults the work to find out how to make his patients well.

As a whole, the work is an excellent *exposé* of what is known about the stomach and the scientific methods of treatment of the day. It has a table of contents and index, and is well printed in uniformity with the "Medical Practitioner's Library" series.

The Practice of Medicine. By Horatio C. Wood, A.M., M.D., LL.D., Professor of Therapeutics and Clinical Professor of Nervous Diseases in the University of Pennsylvania, Member of the National Academy of Science; and Reginald H. Fitz, A.M., M.D., Hersey Professor of the Theory and Practice of Physic in Harvard University, Visiting Physician to the Massachusetts General Hospital, etc. Philadelphia: J. B. Lippincott Company. London: 10 Henrietta Street, Covent Garden. 1897.

Here we have an attempt to view medicine simultaneously from the pathologic and therapeutic sides. Harvard and the University of Pennsylvania are the points of view from which the horizon has been scanned, and the men with their eyes to the small end of the telescope are keen-eyed observers of long experience, who may be relied upon to let no pathologic or therapeutic fact elude their search. While there is a joint responsibility for almost all views entertained by the writers, each has executed by himself certain defined portions of the work. Thus Professor Wood is individually responsible for articles on diseases of the nerves and muscles, acute and chronic poisoning, and all of the therapeutics. Professor Fitz, on the other hand, stands sponser for all that his colleague says excepting where the pronoun "I" indicates the view of one writer alone, and has individually prepared the chapters on most of the infectious diseases, diseases of the blood, circulatory, respiratory, and digestive systems. The first thing one notices on opening the book is that it readily remains open at any given page, indicating an excellence of binding that is only too rare in medical works. Then it is not too heavy to hold comfortably in the hands, a commendable feature in these days of heavy text-books. Many of the topics are but superficially treated, and many diseases are not so fully described as their importance would seem to call for, but this fault, if corrected, would make too heavy a volume. In point of fact internal medicine can no longer be adequately crowded in between the covers of any one volume; either the subject matter must suffer or the student. In the present work little space has been wasted upon forms of treatment and remedies which have not proven themselves of value.

Neurological Reports. Charles L. Dana, M.D.

This is a series of studies reproduced from the *Post-Graduate*, neatly bound but without title page, and hence probably intended for private distribution.

Some attention is given to hypnotism, especially the systematic use of the simpler and suggestive methods. The illustrations inserted toward the end of the book relate to interesting subjects, but a careful reading of the many instructive articles fails to disclose reference to them.

Illustrated Skin Diseases. An Atlas and Text-Book, with Special Reference to Modern Diagnosis and the Most Approved Methods of Treatment. By William S. Gottheil, M.D., Professor of Dermatology in the New York School of Clinical Medicine. New York: E. P. Treat. 1896.

The first three portfolios of this new work have just appeared.

Part 1 deals with the anatomy and physiology of the skin, giving every detail pertaining thereto, together with illustrations of the epidermis, muscles, Pacinian corpuscles, sebaceous glands, hair and hair follicles; typogravure of a case of morbilli and variola, and a photogravure of a case of eczema impetiginosum and of tricophytosis.

Part 2, commencing with general therapeutics of the skin,

deals with eczema and syphiloderma palmæ and continues with a photogravure of lupus vulgaris and psoriasis circinata. The author's classification is one which is a slight modification of that known as Jessner's. The most natural and certainly best illustration is the case of gumma subcutaneum, Plate XXX. This is so natural that one cannot help realizing what it would otherwise be impossible to grasp.

Part 3 commences with seborrhœa and continues with dermatitis venenata. Plate XXVIII., dealing with syphiloderma tuberculo-ulcerosum, is certainly proof of what can be accomplished by illustration. The photogravure of elephantiasis Arabum and the subject of urticaria factitia papulosa, urticaria pigmentosa, and also prurigo, with the case of nævus vasculosus, and the chapter on purpura dealing with subcutaneous hemorrhages, end the third portfolio. Every disease is profusely illustrated. In fact the stronghold of the work is its color photography, depicting as it does from life what heretofore it has been considered impossible to illustrate. The etiology, pathology, and diagnosis are given in as few words as practical, and great space is devoted to modern therapeutics. So we find thirty-eight different formulæ of the author's recipes of lotions, ointments, etc., based on years of extensive experience in both hospital and dispensary practice.

The Mineral Waters of Mt. Clemens, Mich. By Richard Leuschner, M.D.

This is a small brochure which may be had by application to the author, who describes the physiologic action, therapeutic value, and chemical constituents of the Mt. Clemens waters. An analysis of the five different waters is given, and the directions for their application to the various diseases are indicated.

The Profession of Medicine, Its Study and Practice, Its Duties and Rewards. By Charles West, M.D., Fellow and late Senior Censor of the Royal College of Physicians. London: Kegan, Paul, French, Trübner & Co., Limited. 1896.

A little volume of one hundred and fifteen pages, pointing out what material a doctor should be made of and how he should fulfil his calling. Many interesting topics are discussed, including consultations with homœopathists.

The Principles of Theoretical Chemistry, with Special Reference to the Constitutional Compounds. By Ira Remsen. Fifth edition. Philadelphia and New York: Lea Brothers & Co. 1897.

The reputation of the author for thorough scientific work, together with the fact that this work has passed through five editions in a comparatively short time, would be a sufficient guarantee of its worth. Furthermore, it has become a standard text-book, not only in this country, but it has been translated into German and Italian. This edition is cast on somewhat broader lines than the former ones, and all changes required by the advance of science have been made. The main object of the book is to point out, as clearly as possible, the reasons for accepting the prevailing views in regard to the constitution of the chemical compounds, to show that they are the legitimate results of a profound and comprehensive study of chemical phenomena, and that they are the simplest views possible if we accept the atomic theory as the basis of speculation. An interesting chapter on chemical affinity appears and though no theory is advanced the results of the latest investigations are outlined and many data secured, which, it is hoped, will assist in framing a correct theory. We feel safe in saying that it is clearer, more concise, and better adapted to the needs of the student than any other work with which we are familiar.

The A B C of the X-Rays. By William H. Meadowcroft. New York: The American Technical Book Company. 1897.

This is an attractive little volume, written in a style that makes it interesting to the seeker after general information as well as to any who wish to make special study of the subject, or practical use of Professor Roentgen's discovery. The volume contains many very good illustrations. It would enable one unacquainted with electricity to choose and manipulate the apparatus necessary for practical work. The book would prove useful to surgeons who may wish to avail themselves of the information that the *x*-rays can often furnish.

Society Reports.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, February 5, 1897.

Andrew H. Smith, M.D., President, in the Chair.

Operations for Facial Neuralgia.—Dr. Joseph D. Bryant presented a woman, forty years of age, upon whom he had operated twice for facial neuralgia. He had first seen her at St. Vincent's Hospital, 1895, when it was learned that eighteen years before she had had a sharp pain beneath her left eye, and since then had been troubled with pain and some ringing in the ears, etc. She had passed through all sorts of medical treatment for the neuralgia, had been given chloral, phenacetin, etc., but without special benefit. In August, 1895, Dr. Bryant made a circular incision beneath the eye, turned up the lower lid, exposed the infraorbital foramen, chiseled out the bone, raised the nerve out of the groove, freed it back to behind the orbital plate, stretched it, and cut it off. Undoubtedly, however, it was cut off in front of the branches going down to the ganglion. The parts were put back and the face healed promptly. She was relieved of her pain for ten months, but then returned with pain in the lower part of the face or region of distribution of the third branch of the fifth cranial nerve. Dr. Bryant then cut across the zygoma, turned down a flap, exposed the temporal fossa, brought into view the internal maxillary vessels and pterygoid plexus, proceeded down to the foramen ovale, waited for the arrest of hemorrhage, which was considerable for a time, then divided the nerve just as it left the foramen. This was in July, 1896. There had been no pain since that date. The patient had lost a little power in the orbicularis of the eye, but was steadily regaining it. This operation was one usually employed before resorting to Hartley's, or division of the nerve within the cranium but extra dural. Of course it was impossible to say how long the relief from pain would last.

Dr. Walker inquired whether the return of pain was progressive, there having been anæsthesia, then sensitiveness, then pain. Dr. Bryant believed the pain had returned gradually.

Dr. C. L. Dana said he had been very much interested in these cases of facial neuralgia since the publication of his article on their medical treatment last summer. He was constantly seeing cases which had been operated upon, and the last four or five months seven or eight had come under his observation. Some of them had been operated upon in every conceivable way, until all three branches of the trigeminal had been divided. In two instances Hartley's operation had been performed. But in all pain had come back. On the other hand, he had known of cases not operated upon in which the pain had disappeared after six or seven years, either spontaneously or after medicinal treatment. Some cases after long periods of suffering had been promptly relieved by medicinal treatment. It seemed to him possible that the attacking of the nerve surgically might prolong the disease, although it certainly did give relief from pain for a period of six to nine months, and sometimes for eighteen months or two years. According to his observation the pain returned sooner after the second operation than after the first. He thought medical treatment was not always thoroughly tried before surgery was undertaken.

Dr. Beverley Robinson mentioned a case which corroborated Dr. Dana's statement that some patients improved or were cured without an operation. The patient had received many medical and surgical opin-

ions, and he believed that eighteen months ago Dr. Bryant had seen her and advised against an operation at that time. She had since improved markedly, although some pain remained. There was a difference between hospital cases and those seen in private practice, where the patients could follow advice with regard to change of surroundings, etc. Many of the latter class could be made comfortable if not cured without operation. The drug which Dr. Robinson had found gave most relief was a good preparation of aconitine given in very small doses. He inquired of Dr. Bryant whether surgeons generally began with the less dangerous but less radical operations, or resorted to the latter only in the event of recurrence of the neuralgia.

Dr. Bryant believed it was the custom to begin with the less severe operations. He thought there had not been a sufficient number of Hartley operations to judge of the permanency of the relief which it afforded, but lately some cases of recurrence had been reported. In the case alluded to by Dr. Robinson, the pain was not nearly so severe as in the one presented.

Advances in the Treatment of Chronic Cardiac Disease.—Dr. Beverley Robinson read the paper (see page 361).

At the conclusion of his paper Dr. Robinson referred to the experiments of Dr. W. Gilman Thompson, published a number of years ago in the Medical Record and in Wood's "Handbook of the Medical Sciences," during which nitroglycerin was applied to the heart muscle itself and had the distinct effect of producing more active systole than could be produced by any other drug. It was thus proven that nitroglycerin was a direct cardiac stimulant.

Dr. W. Gilman Thompson opened the discussion. The author, he said, had covered a wide field in a very interesting way. Regarding rest and exercise in cardiac disease, one could judge of the amount required when the patient first came under observation only by carefully watching the effect. He recalled a case in which a marked degree of arrhythmia existed for years, and yet the patient was able to go about and take moderate exercise. In instances of that kind one might suppose on first seeing the patient that rest abed was required, whereas it would be a hardship and even do harm. But the amount of exercise to be taken should never be left to the discretion of the patient.

The author had alluded to the use of salicylates in certain cases of chronic cardiac disease, particularly those which had originated from rheumatism. Personally Dr. Thompson had found that they did more harm than good. They tended to promote anæmia. He had been accustomed to limit their use to cases in which there was pain, connected perhaps with pericarditis or endocarditis, and fever. As soon as these symptoms subsided, he thought the salicylates should be discontinued. They certainly did nothing in such cases to prevent cardiac complications, while they did promote or aggravate anæmia, which was very undesirable.

The reader had made some good suggestions with regard to diet. In his own opinion, one of the two cardinal principles in the regulation of the diet was to avoid overdistention of the stomach by flatulence. The mechanical crowding upward of the heart by a distended gastric organ was shown in irregularity of the heart, dyspnœa, etc. That condition could be prevented in large measure by regulation of the diet as suggested by Dr. Robinson, although he believed that special mention had not been made of the fact that it was out of starch and sugar that most of the gas which caused distention was produced. He thought the suggestion to feed the patient often and only a comparatively small quantity was a good one, and was applicable to fluids as well. The heart action being feeble, to throw a large amount of fluid into the circulation at once would necessitate the pumping organ to work harder in moving it around. The amount of fluid taken should be restricted within reasonable limits, but given frequently in small quantity if necessary. In such cases there was also frequently chronic kidney disease demanding diuretics, and one had to choose between overloading the stomach and the vascular system to a degree which might impede the action of the heart and giving too little fluid for the best interests of the kidneys.

Regarding small doses of calomel, the speaker had had such bad results from salivating patients that he felt inclined to give them up. He thoroughly agreed with the author, however, regarding the benefit to be derived from occasional larger doses of mercury in suitable cases. They did undoubtedly relieve a good deal of dyspnœa and engorgement in different organs, and whether one gave blue pill or a single large dose of calomel the result was equally efficacious.

With regard to the stimulating effect of nitroglycerin upon the heart, Dr. Thompson said he was thoroughly convinced that it was a good cardiac stimulant. Its failure to show much effect upon the arterial tension could be referred to its double effect of distending the arteries while increasing the heart's force. He found five grains of chloral an excellent adjuvant to nitroglycerin in overcoming the heart's embarrassment.

Dr. Henry F. Walker thought the most important service which the physician rendered the patient with chronic heart disease consisted in so regulating the diet as to prevent gastric disturbance yet keep up nutrition, and in relieving engorgement of the liver, etc. In his experience the remedies which were directly applicable to the treatment of the heart were usually those which only controlled its nervous irritability.

Dr. F. P. Kinnicutt agreed fully with the author and the previous speakers with regard to diet in chronic heart disease. With regard to mercurials, he thought he had obtained better results from the occasional use of rather large doses than from the smaller doses mentioned by Dr. Robinson. As to chloral, he had found it very usful in connection with nitroglycerin. There was a number of cases in which it was desirable to reduce the arterial tension, and nitroglycerin alone failed to accomplish the purpose even when given in large doses, but on combining with it five grains of chloral, repeating every four or five hours, he had seen distinctly beneficial results.

Dr. Kinnicutt agreed with what he had understood the author to say regarding the inadvisability of invariably trying to relieve arterial tension. Arterial tension was probably a conservative process in some conditions. In cases of increased tension in arteriosclerosis associated with renal disease, it often was a nice point to decide how greatly arterial tension may be lowered without incurring the risk of promoting serous effusions. In cases in which the arterio-sclerosis is associated with dilatation of the left ventricle, which so frequently is the ultimate outcome, clinically, in his experience the best results followed the combined use of digitalis or strophanthus and arterial dilators. Increased force is thereby given to the heart's action and at the same time the resistance in the blood current is diminished. For affecting the sclerosis itself, the routine use of the iodides he believed to be of value.

Nitrite of Sodium as an Arterial Dilator.—The President believed the author had spoken of nitroglycerin as representing the entire field of arterial dilators. It undoubtedly did the work very effectually for a brief period. Some experiments made some years ago had shown that the effect of moderate doses

of nitroglycerin was exhausted in about forty-five minutes. Given in the usual manner, there was likely to be an interval during which the system was entirely without its influence. But there were other nitrites to which this objection of so transitory an effect did not apply. Nitrite of sodium deserved special mention. It caused relaxation of the arteries for three or four hours and its influence was more even. Dr. Smith employed it a great deal in cardiac troubles because it was not necessary to repeat the doses so frequently as when nitroglycerin was used. Now and then the latter might also be added. With reference to the danger of salivation from the use of small doses of mercurials, he thought we were particularly liable to that accident when the kidneys were impaired, as they frequently were in cardiac disease. Moreover, salivation in such cases, complicated with anasarca, was very difficult to control. He preferred blue mass, which had not troubled him in that way.

Dr. Robinson closed. He had not expected to bring out anything particularly new in the paper, but his desire had been fulfilled in calling forth a discussion by a society composed of such distinguished members. One of the points which he had desired to bring out was the proper estimate to be placed upon what might be called the fad of the day, the Schott physical treatment and the Bad Nauheim. There was no doubt in his mind that this could be made a safe treatment, but there was also little doubt that its usefulness was very much exaggerated to-day and that, if it were not governed properly, it was capable of doing a great deal of harm. It was most essential before such treatment was undertaken that the physician should make a most accurate diagnosis of the case as one suitable for it. He supposed all would agree with that view, yet he wished to emphasize it. Another point to which he had wished to call attention was the question of so-called or, perhaps, real hypertension of the arteries. In watching the rising medical men of to-day in hospitals, he observed their fingers always wandering over the radial artery. They found hypertension there often, and always "went for it," usually by giving nitroglycerin. But to administer nitroglycerin in a manner to produce the result which the hospital interne desired would, the speaker thought, produce at times bad effects as well as good. He wished it understood that he agreed with Dr. Thompson and other speakers, that when calomel was given in small repeated doses its effects must be watched very carefully. He used it in this manner less in private than in hospital practice, for the reason that in private practice the patients could not be kept under so close observation. With the latter blue mass was preferable. Moderate doses of nitroglycerin would help along on occasions, but one should not depend upon this drug and increase the dosage to the neglect of matters of more practical moment, such as the use of mercurials, properly watched, for unloading the portal circulation, etc.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 4, 1897.

Edward G. Janeway, M.D., President, in the Chair.

The Health Department of Greater New York.—Dr. Stephen Smith read the first paper. He said the creation of the department of health for the territory of the Greater New York would prove an event of transcendent importance in the history of municipal or State medicine. Whatever the political, financial, commercial, or other advantage or disadvantage which might result from this union of various municipalities into one homogeneous government, there could be no doubt that their consolidation under one well-equipped health department would prove of immense importance to the public interest. There was ample proof of the necessity of bringing contiguous territory under a central sanitary authority. An outbreak of contagious diseases in outlying towns was more serious to New York City at present than when the outbreak was within the line of its well-organized health department. Again, it was of the greatest public utility that the laying of streets, drainage, sewage, etc., should be in accord with sanitary laws.

The creation of the board of health of New York City about thirty years ago was the best piece of legislation still remaining on the statute books, and, being about the first in this country, had been taken as the basis of similar laws in various other municipalities and States. Three points of criticism had been taken, which the reader considered in their relation to the charter of Greater New York: two were general, one specific. The first related to the powers of the health department. It must be admitted that a department clothed with such vast and unrestricted powers was an anomaly in civil government. No other department of the new municipality, no department of the State or of the national governments equalled it in arbitrary and unrestricted power over the person and property rights of the people. The board possessed legislative, executive, and judicial powers without restraint of higher authorities. Such a department was to be tolerated only because it had infinite possibilities of protecting the people against pestilential diseases and securing them health and longevity—the greatest boons which government could bestow. We could appreciate the necessity of giving such powers to the board of health only by a knowledge of the advance made in medical science, more especially as to the bacteriological origin of disease. The flood of light which the bacteriological department had thrown into the dark realm of contagious diseases had revolutionized preventive and curative medicine. The field of operation for preventive medicine was the community in its civil capacity. While the carrying out of sanitary medicine required that the health department be clothed with extraordinary power, yet, if this power were put under the control of incompetent and corrupt men, no method could be devised by which the property and person of the citizen could be more jeopardized.

The second point related to the qualifications of the authorities to carry out the laws. The proposed charter provided for a board of five members—the president of the board of police, the health officer of the port, and three members to be appointed by the mayor, two of whom should be physicians ten years in the practice of medicine immediately preceding their appointment, and one member not a physician, who should be president of the board. Dr. Smith objected to this composition of the board for reasons, some of which follow. He did not believe in *ex-officio* membership, for in nearly all departments such members were mere figureheads until they had some political object to carry out, when they became very officious and usually carried their point. The majority of the presidents of police the past twenty-five years had possessed, so far as he knew, no special qualifications for membership in the board of health. This provision was almost sure to result in introducing politics in its most dangerous form into the board. Nor was there any necessity for making the health officer of the port *ex officio* a member of the board. Being a State officer, he had no direct connection with the city government, usually was not even a citizen of New York City, and was not required to possess any special qualifications

which would make him a useful member of the board.

Dr. Smith objected very strongly to the qualifications required of the third appointed commissioner, which were simply that he should not be a physician and should be president of the board. Practically the law declared that any man—lawyer, clergyman, cobbler, or political tramp—could be president of the board, provided he had not a medical education. The only excuse was that the president of the board should be a business man, but it was a sufficient answer that most of the duties of the board required little knowledge of business; and, if it were otherwise, let it be remembered that in most cities and States the president of the board of health was a physician, and the conduct of their offices presented models of business methods.

Composition of the Health Board as It Ought to be.—The duties of the board of health, Dr. Smith said, could be divided into three groups: 1. Those requiring a knowledge of medicine and the applied sciences. 2. Those requiring practical familiarity with sanitary engineering and allied sciences. 3. Those requiring a knowledge of law. A board having a membership of experts in these three branches of knowledge would be competent to make judicious ordinances, to execute practical work in sanitary matters, and to enforce all legal obligations in proper manner. Dr. Smith thought the proportionate representation in the board of these three classes should be, in accordance with the duties to be performed, as follows: Three physicians, one lawyer, and one sanitary engineer, making a board of five. The doctors should be practitioners of ten years' standing, legal residents of the city; the lawyer a member of the bar association, and in his profession in the city at least ten years; and the sanitary engineer a member of the society of sanitary engineers, and in his profession in this city at least ten years. One of the three physicians should be selected from Manhattan, one from Brooklyn; the third, to be president of the board, should have had at least five years' experience in the health department, and should devote all of his time to the duties of the office. If it were insisted upon, the president of police and health officer of the port could be members, and the balance of power would still rest with the medical members.

Coroners Useless.—Dr. Smith said that no scheme could well be devised which would as certainly fail of its object as the coroner system, from which this State had suffered from colonial times. The duties of this office should be included under the work of the board of health through its bureau of vital statistics. In the bureau of deaths might be an officer called the medical examiner, who should have the necessary number of assistants, and whenever any suspicion surrounded a death they should investigate, have evidence presented before a judicial officer, and if the facts were sufficient have the case go to regular trial.

Approves of the Present Charter.—Dr. George B. Fowler, health commissioner of New York, thought we were fortunate in hearing the criticisms and suggestions of Dr. Smith, who had had so wide experience in sanitary matters. But there had been great advancement and extension in the health department of New York City since Dr. Smith's membership in it. He freely confessed that when he assumed the duties of health commissioner he was not at all prepared to understand the magnitude of the department as it existed to-day. What was necessary to govern the health department of the greater city need not differ much from what governed the present New York. The health board now consisted of the president of the board of police, the health officer of the port, the health commissioner, and a layman who was president. It was extremely important that the board should be free from the bane of politics, and it was, so far as he knew, to-day. Under the beneficent working of the civil-service law, they did not know or care what was the politics of the officers below the grade of commissioner. According to his experience, the board as at present constituted was about as efficient as it could be made. Regarding a lay member being president, he had found there were many duties not medical—concerning the making of contracts for the removal of manure, the drawing of plans for buildings, repairs, and improvements, etc., that a medical man would not care to perform, and could not perform as well as a layman. In a board properly constituted, the president left the medical matters to the medical commissioner. The president of the board of police was of special service in the board in certain cases of emergency. It was necessary that the health officer of the port should be with them in the event of invasion through the port by infectious disease. He doubted whether it was best to make a change. Be it far from him to suggest that there was no medical man who possessed business capacity equal to laymen, but hundreds of things connected with the department did not enter into the life of a physician, and it was a very serious question whether the president of the board should not be a layman.

Brooklyn's View.—Dr. Z. Taylor Emery, health commissioner of Brooklyn, endorsed nearly all that Dr. Smith had said, and then presented some suggestions which he had previously made before the charter commissioners. He would object to a board composed of an even number, as four. He strongly objected to the discrimination against a physician as president of the board. In cases of emergency relating to contagious diseases, the president had sometimes to issue orders before a meeting could be called, and only a physician could properly act under such circumstances. The board required the support of the medical profession, and a physician as president could have greater influence with the profession than a layman. Regarding business qualifications, the president in Brooklyn had been a physician, and he ventured to assert that the business of the board had been as well transacted as in boards with a layman at the head. The new charter limited the number of sanitary inspectors. He thought the number should be left to the discretion of the commissioners. Again, he thought the board should appoint a sanitary engineer, and have the department of plumbing, drainage, and ventilation under the control of the health department, instead of under that of buildings. This had been found the best plan in Brooklyn. Instead of legislating out of existence factories for bone boiling, fat rendering, and the like, he thought it would be best if they were left under control of the board of health. Surrounding counties might object to such factories being driven on to them. Further, the new charter required the separating of ashes and garbage. This should be left to the judgment of the board, for no doubt it would soon be recognized here, as it was in Europe, that it was best to mix them and burn all together. This had been shown abroad to be the most economical, safe, efficient, and sanitary manner of disposing of all refuse. Dr. Emery would place the reporting of marriages, births, and deaths under the board of health.

Staten Island's View.—Dr. Theodore Walser, health commissioner of New Brighton, Staten Island, told of the work of the health board of his town. The board had the plans of every new building, and its consent was required. All but one of the school buildings were new, and had sanitary arrangements approved by the board. He had for fifteen years, as health officer, registered all cases of contagious disease required to be reported, including scarlet fever, diph-

theria, and small-pox. During the past year there had been one hundred and twenty-eight cases of diphtheria, and on investigation he had found that all except four had occurred along the line of a certain open brook, which was filthy. In this matter something ought to be done, and if the charter of Greater New York should be adopted, he would much prefer to appeal to a medical man rather than to a layman as president of the board of health. The town had a crematory for garbage, which worked satisfactorily. The garbage was collected once or oftener every day. There should be something more definite about the cubic air space in schools, etc. If there was to be a new board of health, his town hoped it would be made better, not worse; that it would profit by the change, not be injured. He perferred medical men to deal with.

Dr. J. Walter Wood, health commissioner of Port Richmond, Staten Island, agreed with Dr. Smith in most matters, but said his remark on the laxity of boards of health in the suburbs did not apply to Port Richmond. So far as the office of coroner was concerned, having been coroner himself at one time, he could confirm his statements in that direction. Such a law as Massachusetts had would be better than the present system.

Dr. T. J. Thompson, health officer of Clifton, Staten Island, also endorsed Dr. Smith's paper. In his judgment, the majority of the health board of the Greater New York should be medical men. The minutiæ of the work should be left to the board itself, after it was given sufficiently comprehensive power. But there should be enough laboratories scattered throughout the territory embraced in the city to enable bacteriological examinations to be made as quickly as possible in all parts.

Dr. A. Jacobi was called upon to open the general discussion. He said that, since no motion had been made, he thought the papers, especially that of Dr. Smith, had sufficiently covered the ground and had offered many points which ought to be digested.

An Insult to the Profession.—Dr. Egbert H. Grandin said he had long contended that the clause in the present constitution which prevented a physician from being president of the board of health should be termed unconstitutional, because it discriminated against the individual. Yet it was proposed to perpetuate the insult in the new charter. There had been no argument advanced in its favor which could not be called absurd. He contended that a physician, provided he be competent, knew more about the disposing of manure and the erection of buildings than did a stock broker, a cobbler, or a political tramp.

The People Should be Represented.—Dr. E. G. Janeway asked the vice-president, Dr. Grandin, to take the chair, and discussed the question of the composition of the board. It was one of a great deal of importance. The board had such power that it was absolutely indefensible, in his opinion, that it should be composed of but one member. For the same reason it ought not to be composed alone of physicians. The people would give its mandates less heed than if there were also a lay member. They had a right to be represented. At one time he was for years associated with a lay member, and they had no trouble. But he would like to see some qualification demanded of the lay member. He thought it ought to be a scientific qualification. Regarding inspection of plumbing, drainage, and ventilation, he supposed that when this was taken from the department of health and turned over to the building department, it was done for convenience to architects and others, who previously had been compelled to go to two different departments with offices not in the same building. He thought that now it would be best to return to the former plan. Dr. Janeway repeated that he was very strongly in favor of a lay member in the board. He need not necessarily be president, although there was something to be said on that side. He had heard this argument used: that if the medical member of the board were burdened with the details of the executive work, a man could not be secured with as much ability in other directions as if he were chosen only for the general supervision of the medical department. For his own part, he was not strenuous either way.

Dr. Emery said he did not think it had been the contention of those who thought the medical profession had been somewhat imposed upon by the provision of the charter permitting almost anybody to become president of the board of health except a doctor, that there should be none but doctors members of the board. That was not contemplated. All that was asked for was that a physician might become president, not that the president must necessarily be a physician. Nor was it desired by any to separate the people from the board of health. Yet it did not follow that because a man was a physician he could not be in close contact with the people. He would not place upon the medical profession the stigma that they did not possess executive ability, business qualifications, or even common sense, as this provision in the charter would indicate. He was in hearty accord with Dr. Janeway as to the qualifications of the lay member. He saw no reason why the president of the police board should be a member, but, since he was to be, that fact in itself provided for lay membership.

Dr. Smith said, in the course of some closing remarks, that there was only one place for a lay member, and that was as the business agent of the board. He would not rule him out entirely, but would require that he be a business man and confine his work to the business interests of the board as far as possible.

Medical Expert Testimony.—A resolution offered at the last stated meeting was adopted, empowering the president to appoint a committee of five or seven to investigate the subject of medical expert testimony as now given in courts, and to make such recommendations as might seem appropriate.

Committee on the Charter of Greater New York.—On motion of Dr. Herrick, the president was authorized to appoint a committee of five, to take into consideration the charter of the Greater New York, and report at the next meeting.

SECTION ON OBSTETRICS AND GYNÆCOLOGY.

Stated Meeting, February 25, 1897.

S. Marx, M.D., Chairman.

Remarks on the Diagnosis and Treatment of Extra-Uterine Pregnancy in the Early Months.—Dr. G. H. Balleray, of Paterson, N. J., read the paper. The diagnosis of extra-uterine pregnancy in the early months would depend upon the circumstances of the case, the skill and experience of the practitioner. Nearly all cases were tubal, and the cause was generally believed to be some abnormal condition of the tube. We were indebted to Lawson Tait for placing the pathology of extra-uterine pregnancy upon a substantial basis, and it was he also who had taught us the proper treatment.

Diagnosis before rupture of the gestation sac might present considerable difficulty, but that it was impossible, as some writers had claimed, was far from the truth. The author pretended to no special skill, yet he had been able to make the diagnosis before rupture of the sac in several cases. The histories of two of these cases were read.

The first was that of a woman, who had given birth

in June, 1895, since which time menstruation had been irregular. In March, 1896, she began to have colicky pains, which required morphine. He found her bright, but pale and anæmic: pulse soft, cervix patulous, uterus pushed to the right side by a mass on the left and posteriorly, resilient, not movable, as large as a duck's egg. Dr. Coe saw the case with him, and concurred in the diagnosis of tubal pregnancy and in the propriety of an operation, which was done at the hospital. On opening the abdomen, Dr. Balleray found that each tube contained a fœtus, the tumor on the left being the larger. The patient recovered. The points of interest in this case were: 1, double extra-uterine pregnancy; 2, diagnosis based almost solely on physical signs, the history being simply one of colicky pains; 3, advantage of drainage, for symptoms of shock simulating hemorrhage followed the operation, and if it had not been for the drainage tube, which proved the absence of hemorrhage, he would have reopened the abdomen, and this additional shock would probably have caused a fatal result.

The doctor who called him to see the second case thought it was one of extra-uterine pregnancy. The patient was pale, poorly nourished; last menstruation some weeks previously. Three weeks before she was seen there had been some sharp colicky pains, but not sufficient to cause her to go to bed, and some bleeding for three or four days. She had noticed a shreddy substance in the clots expelled. Pulse soft; temperature, 99° F.; mass at the left of and posterior to the uterus, displacing the uterus slightly upward and to the right. The body of the uterus was somewhat enlarged, the cervix large and soft, as in early normal pregnancy. The patient was being removed to the hospital for operation, and on the way rupture of the sac occurred. On opening the abdomen about a quart of fluid and clotted blood was found and removed; the left tube with fœtus and placenta was removed; the appendages on the right side, being diseased, were also extirpated; the cavity was flushed and drained: the patient recovered.

Some idea of the frequency of ectopic pregnancy could be formed from the fact that at the Paterson General Hospital seven cases had been operated upon the past eight months. Rupture of the sac was sometimes the first evidence of anything wrong. Probably women spoken of as sterile were more liable to extra-uterine pregnancy than others, but it should not be forgotten that all women were liable during the child-bearing period.

The history of ectopic pregnancy was usually about the following: Cessation of menses for one, two, or three months, during which time the patient might or might not experience the usual symptoms of pregnancy—morning sickness, etc. After a time came colicky pains in the lower part of the abdomen, accompanied by the discharge of more or less blood from the vagina. The blood was sometimes fluid, sometimes clotted; occasionally a shreddy substance was mixed with it, or a membranous mass. The colicky pains might disappear and recur at intervals of several days or a few hours. The flow of blood might be continuous, but rarely was profuse. The physical signs were again mentioned in detail, after which the author considered the differential diagnosis from normal pregnancy in a misplaced uterus, from salpingitis, ovarian abscess, small adherent ovarian cyst, pregnancy in one horn of a double uterus, hæmatosalpinx, and hæmatoma of the broad ligament. The clinical history, together with the physical signs, usually enabled one to make the differential diagnosis; but in any event, most of the conditions named called for an operation. If necessary, he should give an anæsthetic and examine per rectum and vagina. The author disapproved of the indiscriminate use of the sound as a means to distinguish between intra-uterine and extra-uterine pregnancy. The earlier rupture occurred in extra-uterine pregnancy the more rapidly fatal was hemorrhage likely to be. When rupture occurred between the layers of the broad ligament, there was a large, soft, boggy mass at one side of and posterior to the uterus, the os uteri in a large proportion of cases pointing directly upward. He knew of no other condition which caused this particular misplacement of the uterus.

The treatment of extra-uterine pregnancy was purely surgical. Whether the diagnosis was made before or after rupture, no time should be lost in operating. Abdominal section was to be chosen in preference to vaginal. If the hemorrhage was limited within the broad ligament, the best interests of the patient were served by keeping her quiet, not operating, allowing blood and fœtus to be absorbed. If suppuration should develop later, prompt action would be required.

Dr. H. J. Boldt thought there was no necessity for removing patients to a hospital after rupture. They should be operated upon at home, and thus avoid the danger attending the transfer. Nor was it conducive to recovery to consume much time in trying to clean out all blood. If some were left and the operation expedited thereby, the patient would be more likely to recover, and absorption of the blood would take place subsequently. Regarding the drainage tube, he felt that we were getting farther and farther from its use. All told, he had seen nearly one hundred cases of ectopic gestation. He had been taught by experience not to operate upon a patient when in profound shock. It simply added to the shock, making it fatal, whereas if one waited a little the patient would rally and an operation could be performed with less danger. Referring to the possible cause of ectopic gestation, the question was surrounded by obscurity. No doubt some form of inflammatory disease was a predisposing cause. He thought that some cases could be explained only on the supposition that the spermatozoa met the ovum in the Fallopian tube, there impregnated it, and development began. The most common variety of ectopic pregnancy was tubal. Seldom did growth go on to term, but was interrupted usually between the second and the eighteenth weeks, more frequently before the tenth week than later. In his own experience tubal abortion was frequent. He believed it might become tubo-uterine, and cited a case, although Mr. Tait strongly opposed this view. Out of sixty-two operations by Dr. Boldt, there had been fifty-eight recoveries and four deaths. Electricity was more dangerous than an operation by an experienced surgeon. Nor was the danger over if the fœtus were killed, as decomposition and sepsis might take place. He would limit the vaginal operation to cases with movable uterus. In advanced cases he would remove the placenta, unless the adhesions were strong. In puncturing for hæmatocele, he would dilate the opening to large size.

Dr. E. J. Ill, of Newark, said ectopic pregnancy was usually first seen by the general practitioner. He had not seen a case among his own patients for three years. He thought diagnosis before rupture must be very difficult. Out of about fifty cases which he had operated upon, there had been only two in which he had made the diagnosis before rupture, and he did not believe that he would have recognized those had the patients not been under treatment for endometritis, and the tumor of ectopic pregnancy developed during that time, along with symptoms of pregnancy. After rupture occurred, the diagnosis was no longer in doubt. In early ectopic pregnancy with rupture there was rarely rise of temperature, and that fact was sufficient to lead one to open the abdomen and find the cause.

Physical signs were frequently negative. He did not remove the whole tube and ovary if any portion could be saved. A woman was better off with part of an ovary than with none at all. He would leave no blood or clots; they might become septic. He preferred the drainage tube to gauze, but the tube must be looked after. Eight subjects had refused operation, and, fortunately for the patients but unfortunately for his reputation, all recovered. But recovery was slow, and, while about forty per cent. might get well without operation, nobody could say what patient would not die, and therefore he always suggested operation.

Dr. P. A. Harris, of Paterson, thought that in the matter of diagnosis of ectopic pregnancy the younger graduates were pretty well informed. The diagnosis was not difficult, and the reason why it was not oftener made was that physicians had not acquainted themselves the past years with the few points necessary for diagnosis. Atypical menstruation in a person previously healthy and colicky pains were symptoms which should excite suspicion. Specialists were not likely to see cases before rupture, unless called by the general practitioner. The speaker had operated in only one case of the kind. As to drainage, he reserved it for cases in which there was septic material. If he believed in leaving blood in the abdomen, he would do as Dr. Boldt did—operate at the patient's home: but as he preferred to remove it, he would have the patient sent to a hospital. Regarding the temperature, while there was no rise in the primary hemorrhage, there was likely to be some subsequently from more or less sepsis.

Dr. Joseph E. Janvrin made some historical references, and mentioned the circumstances which had led him, about 1887, to abandon electricity and resort to abdominal section in ectopic pregnancy. It was his custom to ligate close to the uterus, to remove ovary and tube, to cleanse the abdominal cavity thoroughly. He thought those who had had obstetric and gynecological experience would have no difficulty in making the diagnosis.

Dr. Egbert H. Grandin said he would speak from personal experience, limited to two cases of early ectopic gestation seen in hospital practice and eighteen seen in consultation practice. The diagnosis seemed to him not so simple as some of the speakers had claimed. The symptoms were never the same, except two. The symptomatology given in the text-books was misleading. Too great stress was laid on amenorrhœa, not sufficient on hemorrhages. Great stress was laid on colicky pains, but these were reliable only in rupture. Again, great stress was laid on enlargement of the uterus, which was correct only before shedding of the decidua; after this event the uterus might not be perceptibly enlarged. The two chief guides to the diagnosis in his experience had been the knowledge that hemorrhage was not consistent with normal pregnancy, and the finding of a tumor at one side of or behind the uterus. The tumor was often high and did not approach the vaginal vault; therefore a rectal examination should be made in case of suspected extra-uterine pregnancy. Of the twenty cases, he had himself operated upon fifteen. The subjects had recovered. His conclusion had been that a clean cut was safer than waiting. He had been surprised that at this meeting and at the last meeting of the American Gynecological Society, the opinion had been expressed by some gentlemen that it was not best to operate during shock attending rupture. Why was the woman in shock? Because she was bleeding. To wait while the hemorrhage was progressing, as it was likely to be, the woman would die. In three cases in his own experience the pulse was imperceptible and the belly was full of blood, yet by quick work the women were saved. While patients in whom he had left blood after removing the tube, etc., had recovered, they had given him a great deal of trouble afterward. The assumption was that the woman with ectopic gestation had a diseased tube. How could one know that it was not septic, and that the clots were not septic? It was best to remove it and fill the belly with hot salt solution. As long as the belly was full of hot salt solution the woman would not die of shock. As to drainage, he had resorted to it only in bilateral operations, and then drained through the vagina.

Dr. A. Palmer Dudley believed that in extra-uterine pregnancy the egg in most cases was impregnated on its way to the uterus. One difficulty in early diagnosis was the fact that many of these women denied exposure to pregnancy. He emphatically agreed with those who thought operation should be done without removing the patient to the hospital. He passed a long pair of forceps down alongside the uterus to control hemorrhage while adhesions were being broken up.

Dr. W. Evelyn Porter thought ectopic pregnancy would be recognized early much oftener than it was if doctors were to make it a custom to examine all their cases of supposed pregnancy the first month or two. The most difficult cases to recognize were those of slow hemorrhage. When decided shock from loss of blood was present, the diagnosis became positive.

Dr. Edward W. Peet had made the diagnosis of ectopic pregnancy in one case at the seventh or eighth week; he used both faradic and galvanic electricity, and packed the uterus with gauze three or four times. Some two weeks later the patient had considerable hemorrhage from the vagina, and everything came away from the uterus. Whether the woman aborted of the ectopic pregnancy he did not know, for the mass had disappeared. The question arose, should one always operate? He could not tell whether it was a case of ectopic pregnancy until, as Dr. Ill had said, the abdomen had been opened. There were certain cases which they, the younger men, were not allowed to operate upon, and they had not the facilities for steering them to a hospital and operating for nothing. Was he justified in so treating his patient, or not?

Dr. Louis J. Ladinski wished to corroborate the testimony of the speakers in favor of operating as early as possible, as well as making the diagnosis as early as possible. One could certainly make the diagnosis if he took into consideration enlargement of the uterus, existence of tumor, irregular bleeding, the passing of one period or more, usually pain even before rupture. Operation should not be deferred, even if the patient was in extreme shock. He cited five cases of diagnosis before rupture, but in two rupture took place before the operation.

Pneumonia in Children.—Dr. Griffith (*The Medical News*, December 5, 1896) speaks as follows of this condition: "Among the conditions which render percussion difficult and unsatisfactory in childhood is the peculiar resiliency of the chest at this age. Unless the blow be light and percussion carefully performed, it is very easy to overlook a limited area of dulness which could easily have been found. It is as much or more the sensation of resistance to the finger which we must seek, as it is any alteration of the sound. Too hard a blow makes the whole chest reverberate, and prevents the possibility of local differentiation. I find a series of rapid light blows the best method as a rule. But in spite of the greatest care it sometimes happens that a child will pass through an attack of pneumonia without at any time revealing a dulness on percussion. Indeed, it often happens that the affected side is tympanitic rather than dull."

Therapeutic Hints.

Tentative Thyroid Therapeutics. 1. It has passed the experimental stage in the treatment of myxœdema, and is a specific for that condition. 2. There have been numerous undoubted cures of obesity by its use. 3. The results of its use for uterine fibroids are encouraging and justify further trial. 4. The reports of instances in which it has been used in the treatment of syphilis are favorable, but there are not enough data upon which to base an opinion. 5. It has proven useful in the treatment of psoriasis and lupus. 6. The reports as to its usefulness in goitre are conflicting, but it should be thoroughly tried before operation is determined upon.—Dr. Lindley, *Southern California Practitioner*, November, 1896.

Urticaria.—

℞ Sugar of lead ..... gr. xv.
Dilute hydrocyanic acid ..... ʒ iv.
Alcohol ..... ʒ viiss.
Water ..... to make ʒ ij.

—Dublin Journal of Medical Science.

Malarial Fever in Children.—Dr. Zuckermann speaks well of:

℞ Tinct. of eucalyptus globulus,
Alcohol ..... āā ʒ ij.
Quinine hydrochlorate ..... ʒ ss.
Quinoïdin ..... ↄ i.
Hydrochloric acid, sufficient to make a solution.
Dose: From twenty to forty drops five times a day.

—La Semaine Médicale, 1896, No. 35.

Gall Stones.—Dr. Balfe states that turpentine is best given according to the following formula:

℞ Ol. terebinth .. .. ♏ v.
Syrupi acaciæ ..... ʒ ss.
Sodii sulph. carbolat ..... gr. xx.
Sp. ætheris comp. ..... ♏ xv.
Aq. menth. pip ..... q.s. ad ʒ i.
M. S. To be taken twice or thrice daily.

—Therapeutic Gazette.

Fetid Diarrhœa in Children.—Dr. E. Tompkins speaks highly of the following as an intestinal antiseptic in children:

℞ Calomel ..... 10 cgm.
Sulpho-carbolate of zinc ..... 15 cgm.
Subnitrate of bismuth ..... 8 gm.
Pepsin ..... 2 gm.
Sufficient for twelve powders. Three per diem in a child of one year.

—La Semaine Médicale.

External Hemorrhoids.—Dr. Lewis H. Adler, Jr., gives:

℞ Fl. ext. hamamelis ..... ʒ i.
Fl. ext. hydrastis,
Comp. tinct. benzoin ..... āā ʒ ss.
Tinct. belladonnæ ..... ʒ i.
Carbolized olive oil (five per cent. carbolic acid) ..... q.s. ad ʒ iij.
M. S. Apply often to the parts.

—Medical and Surgical Reporter.

Lumbago.—A formula by Drs. Martindale and Westcott is:

℞ Atropine ..... gr. iv.
Oleic acid (more or less, p. r. n. ..... ʒ i.
Castor oil ..... ʒ i.
Oil of lavender ..... ♏ v.
Rectified spirit ..... q.s. ad ʒ i.

—Medical Times and Hospital Gazette.

Strontium Lactate is a pure diuretic, and is more valuable than any other remedy in the treatment of acute inflammatory conditions of the kidney.—Bronowski.

Uterine Leucorrhœa.—The following is a very useful astringent and antiseptic injection:

℞ Tannic acid ..... ʒ ij.
Pure alcohol,
Beechwood creosote ..... āā ʒ i.
Distilled water ..... ʒ viij.
M. A tablespoonful of this solution mixed with a quart of tepid water, and used as an injection three or four times daily.

—The Practitioner.

Sexual Neurasthenia.—

℞ Quinin. bisulphat ..... ↄ i.
Ferri subcarb ..... ʒ i.
Strychninæ sulphat ..... gr. ss.
Ext. damianæ ..... ↄ i.
Ext. cinchonæ ..... ↄ ij.
M. ft. capsulæ No. xx. S. One after each meal.

—Virginia Medical Semi-Monthly.

Irritable Bladder Due to Excessive Phosphaturia.—

℞ Acid. benzoic.,
Sodii biborat ..... āā ʒ ij.
Aquæ ..... ʒ vij.
S. One or two teaspoonfuls at a time.

—La Médecine Moderne.

Arsenic per Rectum.—In pernicious anæmia, pseudo-leukæmia, etc.

℞ Liq. potass. arsenit ..... ʒ i.
Aq. dest ..... ʒ ij.
S. One drachm injected into the rectum morning and night.

Vinay.

Fever Blisters.—

℞ Camphor ..... gr. v.
Arrowroot, powdered ..... gr. xxx.
Bismuth subnitrate ..... gr. xxx.
Cold cream ..... ʒ iv.

—Monthly Retrospect, September, 1896.

Vaginismus.—Dr. Touvenaint (*New Yorker med. Monatsschrift*) advises the following:

℞ Stront. bromid.,
Potass. bromid.,
Ammon. bromid ..... āā ʒ i¼
Aq. dest ..... ʒ viij.
M. S. Tablespoonful twice a day.

Or,

℞ Zinci valerianat ..... gr. ½.
Quinin. valerianat ..... gr. iss.
Extr. opii,
Extr. belladonnæ ..... āā gr. ¼.
M. ft. pil. No. i. S. From three to six pills daily.

Locally,

℞ Ext. krameriæ ..... gr. iss.
Morphin. hydrochlor ..... gr. ⅓
Ol. theobrom ..... ʒ i.
Ft. suppos. vaginal.

Or,

℞ Cocain. hydrochlor ..... gr. iij.
Extr. belladonnæ ..... gr. iss.
Strontii bromid ..... gr. iv.
Ol. theobrom ..... ʒ i¼
M. ft. suppos. vaginal.

Whooping-Cough.—

℞ Dried thyme ..... 5 parts.
Boiling water ..... 12 "
M. Infuse for ten minutes, sweeten to the taste, and give a tablespoonful every hour.

—Journal des Praticiens, November 28th.

Diphtheria.—Dr. M. S. Barsky (*International Medical Magazine*) recommends:

℞ Pilocarpinæ hydrochloratis ..... gr. ⅓
Ammonii carbonatis ..... gr. xv.
Potassii hydrochloratis ..... ʒ ss.
Aquæ destillatæ ..... ʒ ij.
Spiritus vini gallici,
Syrupi senegæ ..... āā ʒ i.
M. S. Of this mixture, a teaspoonful, a dessertspoonful, or a tablespoonful, may be given every hour, according to the age of the patient.

Sciatica.—

℞ Alcoholic solution of nitroglycerin (one per cent.) ..... ℥ ss.
Tincture of capsicum ..... ℥ iss.
Peppermint water ..... ℥ iij.

Five drops thrice daily in a tablespoonful of water for the first three days, and ten drops thrice daily on the following days.

—Troussevitch.

Flatulence.—

℞ Olei cajuputi ..... ℥ ss.
Tinct. lavand. comp. ..... ℥ ss.
Mucil. acaciæ ..... ad ℥ ij.
S. Desertspoonful when necessary.

—Hartshorne, *Medical Press and Circular.*

Diphtheria.—Dr. Benjamin (*Journal of the American Medical Association*, October 17, 1896), after ten years' trial of the following mixture, reports one hundred cases with one hundred recoveries:

℞ Acidi acet. dilut. ..... ℥ ij.
Pot. chlorat. ..... ℥ ss.
Acidi carbol. ..... gtt. v.
Tinct. ferri chloridi ..... gtt. v.
Pulv. alum. ..... gr. v.
Acidi salicyl ..... gr. i.
Glycerini ..... ℥ ss.
Aquæ rosæ ..... ℥ ss.
Aquæ ..... q.s. ad ℥ iv.
M. S. In severe cases have all the mucous membrane thoroughly sprayed through the nose and mouth at intervals of fifteen or twenty minutes, or even longer, about fifteen seconds at a time, the child breathing as naturally as possible during the application.

He also uses tincture of chloride of iron in large and frequent doses, as he thinks it produces favorable conditions of the blood and benefit is received by its local action while being swallowed.

Pharyngitis Sicca.—This is recommended for the dry throat of this condition (*Gaz. Hebdom. de Méd. et de Chir.*, August 20, 1896):

℞ Glycerin ..... gr. cccl.
Carbolic acid ..... gr. iv.
Tincture of aloes ..... gr. viij.
Tincture of iodine ..... gr. ivss.
Wine of opium ..... gtt. x.
M.

Coryza.—

℞ Uranium acetate ..... gr. ⅜–iss.
Finely powdered roasted coffee ..... ℥ iiss.
M. S. A pinch to be snuffed up the nostril two or three times a day.

—*La Médecine Moderne.*

Dyspepsia and Vomiting in Tuberculous Subjects.—Dr. Barth (*Gaz. Hebdom. de Méd. et de Chir.*) recommends the following:

℞ Prepared chalk,
Calcined magnesia ..... āā gr. iij.
Manganese dioxide ..... gr. iss.
Powdered belladonna ..... gr. $\frac{1}{100}$.
M. For one dose, to be taken after eating.

If there is severe pain, fifteen-one-hundredths of a grain of powdered opium may be added.

Inhalations in Phthisis.—Dr. J. A. Dower (*Brooklyn Medical Journal*) uses this formula:

℞ Iodophenol ..... ℥ ij.
Ethyl iodide ..... ℥ i.
Spiritus vini rect. ..... ℥ ij.
Spiritus etheris comp. (Squibb's) ..... ℥ i.
Aquæ ..... ℥ i.

Uterine Hemorrhage.—Dr. Egbert (*Philadelphia Polyclinic*, October 31, 1896) advises the following when the hemorrhage follows abortion and is attended with subinvolution:

℞ Fluid extract of ergot (Squibb's) ..... ℥ ij.
Fluid extract of viburnum prunifolium ..... ℥ ij.
Tincture of cinnamon ... enough to make ℥ ij.
M. Dose: Teaspoonful in hot water from two to six times a day.

Epistaxis.—In rebellious epistaxis the following is recommended for trial:

℞ Corrosive sublimate ..... gr. i.
Dilute hydrochloric acid,
Tincture of cannabis indica ..... āā ℥ ij.
Ergotin ..... gr. xxx.
Simple syrup ..... ℥ i.
Infusion of quassia ..... ℥ viij.

A large teaspoonful of this solution may be taken three times each day in a glass of water.

—*Revue de Thérap. Medico-Chir.*, June, 1896.

Spasmodic Cough.—

℞ Pot. bromid ..... ℥ i.
Vin. ipecac ..... ℥ iss.
Tr. belladon. ..... ℥ iss.
Syr. tolu ..... ℥ vi.
Aq. ..... ad ℥ iv.
S. One or two tablespoonfuls every three hours.

—*The Practitioner.*

Irritability of the Bladder After Delivery.—Mr. W. E. Fothergill ("Manual of Midwifery") says the following is a very good mixture:

℞ Salol,
Tinct. hyoscyami ..... āā ℥ i.
Infus. buchu ..... q.s. ad ℥ vi.
M. S. A tablespoonful three times a day.

Heart Affections in Early Life.—Dr. Charles Goodwin Jennings (*Pediatrics*) says that from seventy to eighty per cent. of the cases of heart complications in early life are rheumatic. In acute rheumatism in childhood only a minority of those affected escape endocarditis. British collective-investigation statistics give, in males, seventy-two per cent. of heart affections. At every visit to a case of rheumatism the physician should demonstrate the presence or absence of endocarditis. It is an early complication, coming on always in the first week of the disease, rarely after the tenth day. It is not infrequently the first manifestation of the process, the joint inflammation following it.

Burns of the Eyelids.—Burns of the eyelids, whether from lime or steam or an acid, should be treated by the application of sweet oil, while the further application of a lotion of carbonate of sodium, or the slightly moistened powder itself, may relieve the intense pain.—De Schweinitz.

Conjunctivitis.—Conjunctivitis of the milder type usually yields to applications of a boric-acid lotion; if more severe, nitrate of silver (two to five grains to the ounce) should be prudently applied. If the discharge is great, bichloride of mercury, 1 to 10,000, may be employed.—Hare.

Infantile Syphilis.—Dr. J. A. Coutts (*British Medical Journal*) writes as follows of the initial symptoms of infantile syphilis: There is a general agreement that in the majority of cases symptoms appear in the second month of life, and that their primary manifestation is exceptional after the third month has expired. The common expression of a relapse in the later months is the appearance of mucous tubercles. Initial symptoms might, however, appear as late at least as twelve months after birth. After referring to the symptoms and causes of "snuffles," and pointing out the necessity of distinguishing between the syphilitic disorder and the acute coryza of infants which has been described by Henoch, Dr. Coutts discussed the various forms of lesions of the skin, following in the main the classification and descriptions of Dr. Radcliffe Crocker, laying special stress, however, on the diagnostic importance of "syphilitic furuncle" described by Dr. Barlow, an indolent cutaneous swelling with a purplish color, which contains a scanty secretion of ill-formed pus.

New Instruments.

MIDDLE-EAR CURETTE AND OSSICLE FORCEPS.

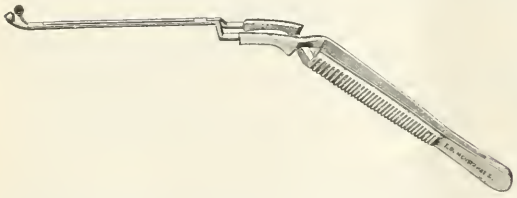
By FRANK ALLPORT, M.D.,

MINNEAPOLIS, MINN.,

PROFESSOR OF CLINICAL OPHTHALMOLOGY AND OTOLOGY, MINNESOTA STATE UNIVERSITY; EX-PRESIDENT, MINNESOTA STATE MEDICAL SOCIETY, ETC.

I DESIRE briefly to call attention to a middle-ear forceps or curette, devised by me and manufactured by E. B. Meyrowitz, New York. I have found nothing like it on the market, so venture to describe it. It is simply an angular forceps, whose confined blades shut by pressure and open by the removal of pressure. The two straight blades are made as delicate as is consistent with strength, and held together by bands—one near the angular bending, the other near the rounded points of the instrument. At about the latter vicinity the two blade ends turn gradually upward and become expanded into two hollow semi-balls, which come firmly together upon pressure with the fingers at the handle, and expand six millimetres upon removing the pressure.

The instrument may be used as a general ear-forceps for the removal of foreign bodies, cerumen, etc.: but is especially designed for the removal of loosened ossicles, polypi, and granulations from the vault of the tympanum. The upward bend of the points renders it easy to insinuate them up into the attic, where



the eye cannot reach. The blunt bullet points render injury improbable with reasonable care. The rounded concavity of the points and their somewhat sharpened edges make it feasible to curette the walls as the blades close, and at the same time to grasp an ossicle which has previously been loosened from its attachments and hold it firmly until it is removed. To an experienced aurist its utility will be apparent at a glance.

Fissure of Rolando.—Dr. Morrison (*British Medical Journal*, 1896, No. 1868) describes the following method of locating the fissure of Rolando: The measurements may be made with a piece of sterilized silk, marked off by knots to form the triangle, or by defining the sides of the triangle by means of the surgeon's finger, whose length is already known. A point is taken half-way between the glabella and the external occipital protuberance, and the breadth of the little finger behind it (about half an inch) indicates the apex of the triangle. An isosceles triangle is then mapped out on the scalp: its sides are three and three-fourths inches long. One lies in the middle line forward from the middle point mentioned above. The base measures four and one-eighth inches, and is anterior. The posterior side of the triangle is over the fissure of Rolando. Trigonometrically the apical angle of this triangle is 67° 27' 52", and this is practically identical with the angle formed by the fissure and the middle line of the skull worked out by other methods, and, from an examination of a large number of skulls of various sizes, is constant and correct.

A NEW NASOPHARYNGEAL CURETTE.

By J. STEWART DOUBLEDAY, M.D.,

PHYSICIAN FOR DISEASES OF CHILDREN, OUT-PATIENT DEPARTMENT, COLUMBIA HOSPITAL; ASSISTANT PHYSICIAN IN CHILDREN'S CLASS, VANDERBILT CLINIC.

HAVING seen no reference in the medical journals to Moure's modification of the Gottstein curette, and being convinced of its superiority to any other instrument at present used in the removal of adenoid growths from the nasopharynx, I take the liberty of calling attention to it. It is composed of two pieces. One piece resembles a large Gottstein curette, the cutting surface looking only downward, and the other fits in closely behind the curette loop with a flexible joint. This sec-

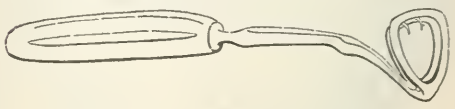


FIG. 1.

ond piece presents two bayonet points a quarter of an inch long. These points are therefore on a plane well posterior to the cutting surface. The handle is well grooved and large, and the faucial curve is good. It was shown to me in an instrument shop in Paris (Mariaud's), several weeks ago. Very few had then been sold, as it was quite new. The favorite instruments for the adenoid operation have been of late the Gottstein curette and the Cohn-Löwenberg forceps. The especial disadvantages of the former are: 1. Excessive hemorrhage from incomplete removal of growth. 2. The slipping away and loss of the growth after removal, in the pharynx or by inhalation into the larynx, with the attendant dangers. With the forceps the dangers are: 1. Incomplete removal unless several excursions are made. 2. The seizure of normal parts. I have used the new instrument in four cases, each time with pronounced success. The little patients were always held in the upright position by a skilled assistant, who also manipulated the mouth gag. At no time was anæsthesia used and suffering did not appear to be great. The operation in each case was almost instantaneous. I brought over two of the instruments and gave one to an associate. He has tried it in three cases with results similar to my own. This gentleman at first thought that the size of the curette was too great. I can only say that one of my cases was in a little girl of three years, the opening to whose pharynx seemed almost closed by the large faucial tonsils. She suffered greatly from dyspnœa, especially at night,

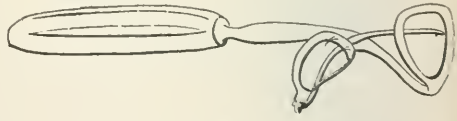

FIG. 2.

great nasal secretion, and very frequent micturition. The adenoid operation relieved all of these symptoms almost immediately. This child had what would be considered a very small nasopharynx. There was, however, ample room for the play of the instrument. The nasopharynx is far larger anyway than is usually supposed. In infants it is very small, but develops rapidly out of proportion to the rate of general growth. The rule governing the use of the Gottstein curette holds good with the new curette also. After the instrument is introduced, pressure must be made downward and backward, not directly downward. In each

of the seven cases which I have seen (five in dispensary, two in private practice) the hemorrhage has been transitory and insignificant, and no ill results have followed operation.

69 West Ninety-Third Street.

Surgical Suggestions.

A New Suture Material. — Dr. L. Arangino has prepared a new suture and ligature from the parietal peritoneum of cattle or horses. This is dissected off, cut into strips of different widths, twisted into cords, and dried for two or three days. These strands are freed from fat by soaking in ether, and are made sterile by soaking in a two-per-cent. solution of corrosive sublimate in alcohol. They are preserved in a weaker solution of the same character. He claims that these sutures can be easily prepared, are strong, are absorbed without difficulty, and are easily sterilized. They are certainly less liable to contain bacteria and micro-organisms than the submucous layer of the intestine, which is the common form of material used as "catgut." Arangino also sterilizes his material by placing it in oil of juniper for ten minutes, heating to boiling, and preserves it in absolute alcohol.

Acute Intestinal Obstruction.—Dr. Sands has classified the causes of acute intestinal obstruction as follows: 1. Errors of position, as intussusception volvulus. 2. Compression, as from inflammatory bands, diverticula, internal herniæ, tumors. 3. Obturation from foreign bodies, as enteroliths, gall stones, polypi, fæcal accumulations. 4. Stricture of the bowels, either fibrous or malignant. To this classification he would add external herniæ and food accumulations.

On Appendicitis.—Dr. Gilbert Barling, in the Ingleby lecture, states as follows. The ordinary positions (of the appendix) are as follows: 1. In this, the commonest, it lies to the inner side of the cæcum, covered by the ileum and extending obliquely upward from right to left. 2. The next most common is, when lying still to the inner side of the cæcum, it passes downward from right to left, reaching to and perhaps extending into the pelvis. 3. It occupies a position to the outside of the cæcum, running upward, it may be, until its free extremity reaches to or even in front of the right kidney. 4. It may be found lying entirely underneath the cæcum, or partly there and partly herniated into certain small peritoneal pouches. Other rare positions may be found, as, for instance, when it occupies the sac of an ordinary inguinal hernia, or some part of the abdomen not the right iliac fossa, the appendix being widely displaced with the cæcum, to which it is attached.

Acute Cystitis.—A very frequent cause of acute cystitis is the decomposition of residual urine. This may quite readily be cured without washing the bladder and without internal medication, simply by drawing off every drop of urine by the catheter every three hours. The catheterization must be done punctually every three hours, day and night, whether the patient urinates or not. Five minims of the oil of wintergreen twice daily, and the ingestion of a gallon of water every twenty-four hours, will contribute to the cure and will greatly hasten it.—*International Journal of Surgery.*

Rupture of the Bladder.—Diagnosis of rupture of the bladder being established, then comes the question of treatment. All ruptures extending into the abdominal cavity should be treated by laparotomy and suture, in such cases as are not too extensive or the edges of the wound too badly lacerated. The suture used should be the Lembert suture, including the serous coat and part of the muscular, care being taken not to include the mucous membrane. Silk is the best suture material, and the sutures should not be placed more than one-fourth of an inch apart and should extend one-half or three-fourths of an inch beyond the tear. After suture the bladder should be injected with a solution of boric acid before the abdominal wound is closed, to test it to see if it leaks. About six ounces of fluid are sufficient. If it should leak, additional sutures should be added to make it tight. Catheterization should be resorted to every fourth hour. Drainage through the urethra or perineum is harmful.—Dr. Magie, *Northwestern Lancet*, December 15, 1896.

Tuberculosis of Superficial Glands.—Dr. De Forest Willard, in a recent paper upon the treatment of tuberculosis of the superficial glands, advises that in their removal great care should be employed to prevent the discharge of pus and caseating material upon the fresh wound. If such an accident should occur, the area should be very carefully cleansed and disinfected. Temporary drainage is to be advised when infection has occurred from such discharges, but in operations with clean enucleation, primary union without drainage can be secured. In removing the glands from the axilla, the same care should be employed as in the removal of carcinomatous nodules. In the groin many difficulties may be encountered, especially if the indurated glands extend deep about the femoral or saphenous veins. With patients who absolutely refuse operation, local and constitutional measures must be employed, including tuberculin and orrhotherapy. The writer has more confidence in the local effects of iodine upon tuberculous granulations than in iodoform. He has had good effects from stimulating the cell growth by a mixture of aristol with nuclein applied locally. His conclusions are that tuberculous infiltrated glands should never be allowed to remain and contaminate the general system.

The Medical and Surgical Treatment of Appendicitis.—Dr. S. C. Gordon (*The Journal of Medicine and Science*) forms the following conclusions in an interesting paper on the above subject: "1st. That appendicitis is always to a greater or less degree peritonitis. 2d. That it is much more frequent than formerly, and due, in my opinion, to germs caused by the epidemic of influenza that has so generally ravaged the world. 3d. That salines have been successful in peritonitis from other causes, far beyond any other form of treatment, and in my own practice and that of many others in appendicitis never doing harm. 4th. That a majority of cases must be in the hands of men who are not experts in surgery and must be treated medically, and modern experience and common sense dictate the cathartic rather than the opium plan. 5th. That the opium method masks symptoms, checks elimination of toxic elements, and causes stasis in the blood-vessels, by paralyzing the vasomotor nerves, thus favoring gangrene. 6th. That the saline plan promptly relieves pain, washes out the toxic elements, and, most important of all, unloads the distended vessels, thus preventing gangrene and maintaining the integrity of the limiting membrane, formed by exudate, even in suppurating cases, and saves life until surgical aid is required or can be obtained (in cases demanding immediate operation). 7th. That in cases of well-marked limited abscess or general suppurative peritonitis, early operative procedure should be instituted, but in all cases such operation should be preceded by the saline treatment. 8th. That by following the above general principles ninety-five per cent. will go safely through the first attack, and often seve-

ral subsequent ones. 9th. That a large percentage of subjects undoubtedly fully recovers after one or more attacks, and no recurrence ever takes place. 10th. That inasmuch as there are no indications whereby we can determine which subjects will fully recover after one attack, it is safer to advise operation before a second one, especially as the organ is diseased to a greater or less degree."

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 6, 1897:

	Cases.	Deaths.
Tuberculosis	227	121
Typhoid fever	4	3
Scarlet fever	170	10
Cerebro-spinal meningitis	2	1
Measles	156	10
Diphtheria	212	28
Laryngeal diphtheria (croup)	10	4
Chicken-pox	20	0

A Good Law is about to be enacted in Belgium making the physician who associates himself with one who practises illegally or in an unauthorized manner, so that the latter is protected by the diploma of the former, equally guilty and amenable to the laws as an accomplice.

The First Operation Under Ether in England.—The essays and addresses of the late Sir Russell Reynolds have just been published in book form. The scene (which he describes as an eye witness) of the first operation under anæsthetics possesses peculiar interest to Americans, and we therefore give it in the author's own words: "It may be interesting to many here to recall, and to some others to learn, that the first operation in England performed under an anæsthetic (ether) was witnessed in University College Hospital and was done by our great surgeon, Liston. Peter Squire, the father of scientific pharmacology in England, having become acquainted with the use of ether as an anæsthetic in America, administered it experimentally to his nephew, William Squire, who was then a pupil of our college, and rendered him quite insensible. He was the first to undergo the process in England. William Squire and I were fellow-students, and he administered it to me shortly afterward, as I wished much to know in what order the senses became extinguished. Those mixed senses, smell and taste, went first, then sight, then touch and the capacity for appreciating pain, and then *longo intervallo*—hearing. They, the senses, came back in inverted order, hearing being an easy winner in the race. The day after this observation was made there was a field day in the hospital, and Liston had consented at Peter Squire's request to try the anæsthetic. I can see him now, as he said to the students with playful eye and doubtful, almost scornful mouth: 'Gentlemen, we are going to try a Yankee dodge for making men insensible. This man's leg has to come off above the knee and Mr. Squire is going to give him ether, so that he wont feel it.' When Squire was giving the anæsthetic Liston leaned against a bench, trying the point and edge of his long amputating knife and smilling incredulously as the poor owner of the doomed leg hissed and snorted under the process of inhalation. Ether was not so pure and an apparatus for its administration not so handy in 1848 as they are in 1888, and so perhaps Liston was a little impatient to get to his work; but at length Peter Squire said: 'He is quite ready now, sir.' Liston's knife flashed in the air; I took out my watch to count the time, and the leg was on the floor in six and twenty seconds. As if it were yesterday, I remember the expression of Liston's face as he turned round to us students and said: 'This Yankee dodge, gentlemen, beats mesmerism hollow.'"

"Pour Sauver l'Innocence" of his young lady patients, a French surgeon diagnosticates uterine disorders and investigates pelvic symptoms through a suprapubic incision rather than introduce the index per vaginam.

"Pediatrics" appears in a new outside cover this year, in which the owls have less of the all-night look. There is also less filigree work, which adds to the dignity of Dr. Brown's excellent little semi-monthly.

Inebriety in Russia.—The Society of Neurologists and Psychologists of Moscow has appointed a special committee to report upon the present state of inebriety in that city, and to draw up a plan for the erection of a hospital for inebriates.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

EATING AND DRINKING. By Dr. Albert H. Hoy. 12mo, 304 pages. A. C. McClurg & Co., Chicago, Ill. Price $1.50.

LECTURE ON APPENDICITIS AND NOTES ON OTHER SUBJECTS. By Dr. Robert T. Morris. Second edition. 8vo, 173 pages. Illustrated. G. P. Putnam's Sons, New York.

THE MENOPAUSE AND ITS DISORDERS. By Dr. A. D. L. Napier. 8vo, 307 pages. Illustrated. The Scientific Press, Ltd., London. Price 7s. 6d.

A SYSTEM OF PRACTICAL MEDICINE. By American Authors. Edited by Dr. A. L. Loomis and Dr. W. G. Thompson. Vol. I. Infectious Diseases. 8vo, 985 pages. Illustrated. Lea Bros. & Co., Philadelphia, Pa. Cloth, $5.00; leather, $6.00; half morocco, $7.00.

THE DISEASES OF THE STOMACH. By Dr. C. A. Ewald. Translated by Dr. Morris Manges. Second edition. 8vo, 602 pages. Illustrated. D. Appleton & Co., New York.

GENITO-URINARY SURGERY AND VENEREAL DISEASES. By Dr. J. W. White and Dr. E. Martin. 8vo, 1,061 pages. Illustrated. J. B. Lippincott Company, Philadelphia, Pa.

LECTURES ON RENAL AND URINARY DISEASES. By Dr. Robert Saundby. Second edition. 8vo, 434 pages. Illustrated. W. B. Saunders, Philadelphia, Pa. Price, $2.50.

A MANUAL OF THE PRACTICE OF MEDICINE. By Dr. A. A. Stevens. 8vo, 511 pages. Illustrated. W. B. Saunders, Philadelphia, Pa. Price, $2.50.

A PRACTICAL TREATISE ON DISEASES OF THE SKIN. By Dr. J. N. Hyde and Dr. Frank H. Montgomery. Fourth edition. 8vo, 808 pages. Illustrated. Lea Brothers & Co., Philadelphia, Pa.

A MANUAL OF PHYSIOLOGY. By Dr. G. N. Stewart. 8vo, 706 pages. Illustrated. W. B. Saunders, Philadelphia, Pa. Price, $3.50.

ESSAYS AND ADDRESSES. By Dr. J. Russell Reynolds. 8vo, 307 pages. The Macmillan Company, New York. Price, $4.00.

DISEASES OF THE GENITO-URINARY SYSTEM AND SYPHILIS. By Dr. F. E. Doughty. 8vo, 441 pages. Illustrated. Boericke & Tafel, Philadelphia, Pa.

INJURIES AND DISEASES OF THE EAR. By Macleod Yearsley, F.R.C.S. 12mo, 40 pages. The Rebman Publishing Company, Ltd., London.

ELEMENTARY BANDAGING AND SURGICAL DRESSING. By Walter Pye, F.R.C.S. Seventh edition. 16mo. 218 pages. Illustrated. W. B. Saunders, Philadelphia, Pa. Price 75 cents.

SCIENTIFIC PSYCHOLOGY.[1]

BY EDWARD BRADFORD TITCHENER, M.A., PH.D.,

ITHACA, N. Y.,

SAGE PROFESSOR OF PSYCHOLOGY AT THE CORNELL UNIVERSITY, F.Z.S., ... BER OF THE NEUROLOGY SOCIETY OF LONDON, COEDITOR OF "MIND" AND OF THE "AMERICAN JOURNAL OF PSYCHOLOGY."

THE object of this paper is to show, in very broad outline, and principally by the aid of illustrations drawn from the physical or natural sciences, in what sense the modern psychologist is justified is speaking of his subject as a "science," and how his treatment of its problems differs from that of the older "unscientific" psychology.

No one, I think, will dispute the fact that the subject matter of science is human experience. The special sciences, it is true, deal only with parts of experience—the physical or natural sciences with facts of experience conceived of, by abstraction, as independent of the observer who records them; the philosophical or mental sciences with facts of experience in their dependence upon the observing individual. But all alike deal with experience, under one aspect or another. Science is, in the first instance, a statement of human experiences.

But human experience is fragmentary; and we are accustomed to restrict the term "science" to a coherent and organized body of knowledge, of recorded experiences—to something that makes up a whole of knowledge, a system. Plainly, then, science is not simply a statement of human experiences. It is a statement of human experiences to which something has been done, which has been somehow worked over, and thus made systematic and unitary. That being the case, it is of the very utmost importance, when a new mass of recorded experiences comes into the field, to know precisely how this working over should be done to bring order out of chaos and make a science out of bare facts.

Facts may be systematized in two ways. To systematize in the first way is the supreme work of the scientific genius; to systematize in the other way is the most heinous sin of which the man of science can be guilty. The first way is that of supplementing facts by hypothesis; the second way is that of transcending facts by speculation. It is difficult, except by illustration and example, to make clear the precise difference between these two processes—all the more, since in any given science there will always be theories which may plausibly be placed under either rubric. But we must make the attempt, in general terms, before having recourse to concrete cases.

To "supplement" is, by derivation, to fill up; to "transcend" is, by derivation, to climb over. In these two root ideas we have the key to the difference of meaning. When we supplement, we fill up a gap in our record by a hypothetical record of the same kind; when we transcend, we fill out a gap by material taken from some other domain of experience, foreign to the material of the record. In the first case, we patch up a hole in a brick wall by laying in other bricks, as nearly of the make and pattern of the original as we can find; in the second, we fill up the hole, say, by affectionate remembrances of the architect who built the wall. The affectionate remembrances may fill a gap in our conversation with the architect's friends; they cannot mend the wall. This supposed instance, absurd as it is, may serve to emphasize the fact that scientific supplementing keeps to its own kind of experience; that when we commit the error of transcending experience we are really climbing out of our proper sphere into another where we have no business.

The history of any science may be summed up in the phrase—from speculation to hypothesis. At first, experience is transcended at every turn. Primitive man sees in the thunder cloud not a result of evaporation and condensation, but an angry giant, storming the gates of heaven; in the stone or branch that catches his foot, the manifestation of some hostile demon, who is seeking his injury; in the ill-fortune of his tribe by war or famine or pestilence, the working of a spell cast by an enemy more skilled in magic than his own medicine men. By slow degrees all this changes; but how slowly there are perhaps few except special students of the sciences who realize. And though every one smiles nowadays at the simplicity, the unscientific fancifulness of primitive man's explanations of nature, I am not so sure that every one knows just why he smiles. Even in the realm of physical science it is not so easy to separate hypothesis from speculation, as I said just now; while in the case of psychology the great majority of the general educated public is, I venture to think, almost entirely at sea as to what constitutes legitimate and what illegitimate theory. I purpose, therefore, to take a series of examples of transcendence from various sciences, in order that we may be quite clear about our fundamental principle, before we go on to consider psychology itself.

Let us begin with physics, the "mother of the sciences," as Bacon called it. The stock instance of exploded speculation in physics is the familiar phrase, Nature abhors a vacuum. It is surprising to realize that that statement held its own so vigorously in the history of physical science that when Robert Boyle published his refutation of it, along with that of several other erroneous theories, in 1666, he felt obliged to call his book "Hydrostatical Paradoxes." And yet the phrase transcends experience in a very obvious way. It personifies nature, and makes one of her emotions, the emotion of horror or abhorrence, the cause of a physical phenomenon. If it is objected that we should not press that meaning, that the statement must not be taken literally, I reply that it was,

[1] This paper contains the substance of an address upon the "Principles and Methods of Modern Psychology," delivered before the Tompkins County Medical Society, January 27, 1897. The address was followed by a series of demonstrations, in which the psychological application of the general principle set forth in the paper was illustrated in detail.

Most of the instances of transcendence here cited will be found in Whewell's "History of the Inductive Sciences" (3 vols., 1857); Butler and Armstrong's "Chemistry" (Enc. Brit., 9th ed.); Burdon Sanderson's "Ludwig and Modern Physiology" (Science Progress, March, 1896). The reader may also consult Kuelpe's "Introduction to Philosophy" (1896, trs. 1897).

as a matter of fact, used as a principle of explanation, and that however you refine upon it you cannot get rid of the underlying transcendence. Or take another instance. The Aristotelian physicists of the time of Galileo maintained that heavy bodies fall downward with a speed exactly proportional to their weight. The reason was simply this: There are four elements, of different weights. Each element tends toward its own place—earth lowest, water above earth, air above water, and fire above air. Hence the heavier the body, the greater its effort to get below other bodies. The transcendence is of the same kind as before: the elements are personified, regarded as in a certain sense wanting to perform their duty, and being satisfied when they have reached their appointed position.

In chemistry, to turn to another science, we find the tendency to personification continuing as late as it did in physics. Van Helmont, whose name every one knows as the inventor of the word "gas," believed that water was the ultimate principle from which all substances are derived. There is in the world, however, besides water, an *archæus*, a formless ultimate something. This something generates the different bodies from water, to which it is attracted by—an odor! And this was as late as the seventeenth century—Van Helmont lived from 1577 to 1644.

The century following the death of Van Helmont is known in chemistry as the phlogiston period. Phlogiston means "combustible," and the word was used to designate an element—the matter or principle of fire, not itself fire—which, along with water, acid, and earth, made up the various chemical compounds. When a body burns, it parts with its phlogiston; if it will not burn, it has already parted with its phlogiston. Most combustibles are insoluble: phlogiston is of a dry character. Metals are made heavier by being passed through a furnace: then phlogiston must be the principle of levity or negative weight. And so on. Now the modern chemist has wholly discarded this principle. Evidently, then, it transcended experience. The transcending, however, is not nearly so obvious as in the previous instances that I have taken. The theory was founded upon experimental data, and explained, in a way, many facts of experience that had hitherto resisted explanation. Nevertheless, the transcending is there. For the phlogiston theory is not a supplementing in kind; it is not, to take our old metaphor, a filling out of a gap in the scientific edifice by bricks of the same kind as those whose value time has proved. It resembles rather the running up of a cross wall to support the old structure—a wall whose materials are perishable, and whose plan does not fall in with that of the whole building. The old builders are not to be too severely blamed; scientific criticism had not developed, a century and a half ago, to anything like its present level. But while we do not blame, we may at least take warning.

The phlogiston theory received its death blow at the hands of the great Lavoisier (1743–1794). And Lavoisier's argument against it was practically that which I am urging now: it was a transcendence. All the phenomena of combustion, he said, were explicable without it, while, on the other hand, there was no evidence of the existence of the principle. Or, to quote the words of Davy, written in 1814: "It was the glory of Lavoisier to lay the foundation of a sound logic in chemistry, by showing that the existence of this principle, or of other principles, should not be assumed where they could not be detected."

Let me take one more instance from chemistry—an instance that brings us down to our own times. There are many series of chemical compounds in which occur terms of, *e.g.*, the character PCl_3 and PCl_5, or N_2O_3 and N_2O_5. That is to say, a certain number of atoms of one element may hold a greater or a less number of the atoms of another element. The explanation given until quite recently of this curious fact is as follows: Each atom of the first element has a certain affinity for atoms of the second; or, if we count each of the latter atoms as one, as a unit, each atom of the first has a certain number of units of affinity for the second. Thus P has five units of affinity for Cl. But sometimes not all of the units of affinity are engaged in the particular compound; and when that is the case, the disengaged atoms satisfy each other. In PCl_3, for example, only three units of affinity are engaged: the other two are satisfying each other. It is clear, at once, that this explanation transcends experience; the notion of affinity is as dangerous and as superfluous as the notion of phlogiston. Modern chemists have recognized that, and speak not of affinities and satisfactions of the atoms, but only of saturated and unsaturated compounds. PCl_5 is a saturated, PCl_3 an unsaturated compound; the one cannot, the other can, take up more atoms of Cl. Now this is not supplementing; but it is a wise refusal to try and pass beyond the bare facts in a case in which that passage must, as knowledge stands to-day, involve transcendence. We naturally think of the term *x*-rays as evidencing a similar wise abstention from speculation in the physical sphere.

I turn now to the two great sciences of organic nature, biology and physiology. Modern biology and modern physiology both owe their origin to a somewhat abrupt change from speculation to hypothesis, from transcendence to supplementing.

Up to the middle of the forties of the present century, physiology was bound in the chains of a fatal transcendence. The method of the physiologist consisted essentially in this: that you should explain everything that you could on the analogy of inorganic nature; that you should regard the living body, so long as you could, as a machine; but that, when anything occurred which was not explicable from that point of view, you were justified in putting it down to vital force. Vital force was, therefore, a power or faculty residing in the living organism, and not found outside of it; and those aspects of the living body which rendered it different from things not living were the result of the action of vital force. Now about this notion of vital force, three things may be said: (1) It puts a premium upon faulty observation; it checks analysis. If you are always liable, no matter how far you have carried your physical explanation of some living function, to be stopped outright by a manifestation of vital force, which you cannot go behind, what is the use of carrying on your physical analysis at all? Why not say at once: "This is thus, because the animal is alive"—and have done with it? (2) The idea of vital force transcends experience. What you have before you are the phenomena, the facts of living; not the facts of vital force. To assume vital force is to speculate, not to make hypothesis; it is running up a new wall, not building within the structure of the science. And (3) vital force gives no explanation of what it pretends to explain. A process in the living body is no more explained by calling it "vital," than a process of combustion is explained by calling it "phlogistic."

In 1847 four men met at Berlin—three of them already friends, the fourth at that time a stranger to the rest. Their names were Helmholtz, Bruecke, du Bois-Reymond, and Ludwig—all now, alas! names only. These four men were steadfastly resolved to constitute physiology upon a physical and chemical foundation, and to give it equal scientific rank (as one of them wrote years later) with physics. Life, for them, was not a sum of manifestations of an unknown and transcendent force: life was a group, a total of physical and chemical processes, complicated, it is true, beyond the usual complexity of either science,

but none the less physical and chemical in their nature. And that is the principle of modern physiology; that is the fundamental hypothesis which is being worked out in detail in modern physiological laboratories; that is the thesis which the individual physiologist maintains and illustrates, so far as in him lies. And those who know modern physiology know what immense progress has been and is being made, how ample the harvesting of results has been and still is, since the day when "vital force" dropped out of the vocabulary of science.

If we date the rise of modern physiology from the year 1847, we may date that of modern biology from the year 1859—the year which saw the publication of Darwin's "Origin of Species by Means of Natural Selection." It is hardly necessary to state what in this case was the transcendence, and what was the hypothesis which replaced it. Special creation has given way to evolution and descent. This is to us a matter of course; we think in terms of evolution; we apply the idea of evolution in all sorts of departments; we have customary metaphors and phrases that imply the notion of evolution; we take it for granted that when a new biological laboratory is equipped, it will be equipped on evolutionary principles, furnished with the means of tracing out with still greater minuteness than has yet been done the course of organic development and differentiation. Yes; when a science ceases to transcend experience and is able to supplement it, then that science can do wonderful things indeed.

And now, what of psychology, to which all this introduction was to lead up? Modern psychology, like physiology and biology, has become a science by the passage from transcendence to experience, from speculation to hypothesis. If dates must be given, it is probably pretty true to say that modern psychology arose in the seventies of the present century, with the publication of Wundt's "Principles of Physiological Psychology," in 1874, and the opening of the first psychological laboratory at Leipzig, in 1879. And the manner of its arising was as follows:

Psychology is—so the traditional definition tells us—the science of mind. Now, just as the older physiologists regarded the phenomena of living matter as the expression of a vital force, so did the older psychologists regard mental phenomena as the expression of a mental force. It was supposed that mind was a real being, one and indivisible, a sort of thing or creature, which took up its abode within some individual body, and from that body manifested the various powers with which it was endowed. The powers were three in number: (1) The power to know, judge, perceive, and reason; (2) the power to suffer and to enjoy; and (3) the power to choose and act. By the first power mind manifested itself as intellect, by the second as feeling, and by the third as will. Plainly, there could be no science of psychology on that basis. The same remarks hold against this notion of mind as against the vitalistic speculation of physiology. Analysis is killed; you may be met at any point of your inquiry by some unexpected, unforeseen, incalculable act of the irresponsible being that you are examining. Experience is transcended: you have in experience mental processes, facts, not manifestations of a being, an entity. And nothing is explained by the speculation. To say that a certain bit of experience, an idea, or a wish, is a manifestation of the thinking or willing mind, is simply to cloak your ignorance by a word.

The first thing that psychology had to do, then, in order to become a science, was to get rid of this mind. And so there arose the curious saying that the new psychology, the new science of mind, was a psychology without a mind; was "Hamlet" with the part of *Hamlet* left out. So it was—a psychology without the mind of the older speculative philosophers. But not in any other sense. Just as you may say to-day that physiology is the science of life, meaning by life the sum total of vital processes—*i.e.*, of the physical and chemical processes that run their course in the living body—so you may say that modern psychology is the science of mind, if you mean by mind the sum total of mental processes that run their course in our experience. If you mean by "mind" some being which is sitting inside you, reading and understanding these lines, then psychology is not the science of that mind. But if you mean by mind the mental experiences that you have in reading—the visual ideas of the words, the feelings of satisfaction or dissatisfaction with their meaning, the pressure of your chair and clothes, the taste of your cigar, etc.—then psychology is the science of mind; for it undertakes to analyze out all that tangle of mental processes, and to discover the laws and uniformities which govern their connections and disjunctions. The new psychology is the science of mental processes.

Now I think that I hear two objections, natural objections, to this exposition. In the first place, it may be urged: You say that you have got rid of "mind," in the old unscientific sense, and yet you speak confidently enough of "mental" processes. What is a mental process, if it is not a manifestation of a real unitary mind? The answer is given with a statement made at the outset of this paper. I said there that experience could be looked at by abstraction apart from the experiencer, or that it could be looked at as dependent on the experiencer. The first way of looking at experience is the way of the natural sciences; the second is that of the mental sciences. Take an instance: A piece of wood and a piece of metal lie in a cold room. The physicist tells you that their temperature is the same, so many degrees. Your sensation tells you, if you lay your hand upon the objects, that the metal is a great deal colder than the wood. Both of these things are facts: but the physicist, in his statement of the matter, abstracts from the sensation of the experiencing individual; the psychologist, in his statement, thinks only of the dependence of experience upon the experiencing individual. Or again: To the mathematician a triangle is not equilateral unless its three sides are measurably equal; to the psychologist any triangle is equilateral which the experiencing individual takes to be equal sided. Measurements can be made in the latter case as strictly as in the former; but the results of measurement are different. A mental process, then, is a process of experience conceived of as dependent upon the experiencing individual.

The second objection that I foresee is of a different order. Is not this doing away with a real mind, it may be said, a dangerous doctrine, likely to upset thinking, and possibly to lead in the long run to materialism? The answer here is twofold. If a thing is scientifically true, it has to be accepted, whether it lead to one "ism" or another. Nothing is gained by shutting your eyes to the truth. But, secondly, the whole text of the present paper should show that modern psychology cannot lead to materialism. For the formula of the materialistic philosophy runs: Mind is material, the outcome or function of matter. The proposition sounds simple enough; and yet it conceals no less than two transcendences. In the first place, what is matter? We must remember that experience is, in itself, unitary, a whole. We can abstract from various aspects of it, for the purposes of human knowledge; but that abstraction does not really divide it up, cut it into parts. Now "matter" is a sort of personification of the independent aspect of experience; those elements of experience which are independent of the experiencing individual have been abstracted from the whole of experience, and set up by themselves, under the name of matter, as if they

existed by themselves. Of course they do not; and the scientific man who knows anything of the foundation of science in the nature of human knowledge knows that they do not—that matter is only a working hypothesis for certain sciences; an abstraction, not a reality. Hence to make this "matter," which we have abstracted from experience, the one fundamental thing in experience, is obviously to transcend experience, to fall into speculation. But again: Mind is said to be material, the outcome of matter. But mental processes are defined by attributes that are quite different from the attributes whereby we define matter: and the laws of independent experience are quite different from the laws of dependent experience. Materialism, that is, not content with having set up a one-sided abstraction as the ultimate and final reality in the world, now goes on to pick up the other half of experience, which it had previously disregarded, and to make that half of the same kind as the first, the abstracted half; and this in defiance of the fact that the second half is in its characteristics very different from the first, and that it is one of the first rules of logical thinking not to argue out of one department of thought into another. We should not argue that because a man is a good husband, therefore he is a great mathematician; and yet materialism makes precisely that mistake—bringing together two aspects of experience which are altogether different and distinct.

No; modern psychology does not lead to materialism or any other "ism," any more than physics does. It pursues its course without regard to anything outside itself. The metaphysician may take its principles, if he will, just as he may take the principles of the other sciences and work them up into a single self-consistent scheme of the universe. And the teacher may take its results, if he will, and work them up into a system of pedagogy; just as the results of physics are utilized in engineering, or the results of chemistry in the making of dyes and perfumes. But the science itself is a very Gallio, and cares for none of these things.

DISARTICULATION AND EXCISION OF THE LOWER JAW ENTIRELY FROM WITHIN THE MOUTH (WITHOUT A SCAR).

By JOHN A. WYETH, M.D.,

NEW YORK.

I FIRST removed one-half of the lower jaw, disarticulating at the temporo-maxillary joint, in the case of Sarah Jacobs, thirty-eight years of age, in the Mount Sinai Hospital on January 6, 1890. Chloroform was administered, the patient being placed on her left side and the face turned sharply downward so that the blood would escape freely from the mouth and away from the larynx. The teeth on the left (the diseased) side of the jaw were extracted, and the orbicularis oris was widely dilated by four retractors properly inserted. The bone was then divided with the chain saw and cutting forceps near the symphysis menti. With the elevator the periosteum was carefully raised and the bone disarticulated. The wound was immediately packed with sterile gauze, which was removed two days after the operation and not renewed. The patient was discharged cured on the 24th of that month. As soon as the operation was completed, the remaining half of the lower jaw was wired in line with the teeth of the upper jaw of that side and held in this position until the patient, three weeks later, was ready to be fitted with an artificial apparatus. This apparatus, made by a dentist, was intended to enable the patient to chew her food by keeping the teeth in line and preventing the remaining half of the jaw from being drawn toward the median line by muscular action. The last time I saw her after the apparatus was applied, it was working satisfactorily.

The same operation was performed in the case of M. G—— , aged eighteen years, who entered the Polyclinic Hospital on November 17, 1895. Family and personal history negative. The diagnosis was osteo-sarcoma. One year previously, she noticed a painful swelling on the right lower jaw. There had been no injury and no defective teeth on that side. An exploratory incision and microscopical examination confirmed the diagnosis of sarcoma. Operation, November 21st. The mouth was stretched with four silk retractors inserted through the lips at points equi-distant and held by assistants. The patient was placed in the lateral position with the mouth dependent. A tooth was extracted near the symphysis menti and the bone here divided with a sharp chisel and cutting forceps. On account of the malignant nature of the neoplasm, the soft tissues were divided with the scissors well away from the growth, sacrificing the lining membrane of the buccal wall and the floor of the

FIG. 1.—M. G. Removal of Left Half of the Inferior Maxilla without External Incision.

mouth. The operation was done rapidly, and gauze was packed in to control bleeding as the exploration was being made. When all the tissues were free beyond the angle of the jaw, leaving only the ligaments and the insertion of the temporal muscle, the operation was completed by seizing the bone above the ramus with a lion-jaw forceps and twisting a number of times in one direction until the ligaments were ruptured, allowing the coronoid process to be drawn down and the insertion of the temporal muscle divided with scissors. Twisting the artery prevented hemorrhage of any note from this vessel. The cavity of the wound was packed with sterile gauze and the remaining half of the law wired in position as in the preceding case. The condition of the girl a year after the operation is shown in the accompanying photograph from an untouched negative. She could not afford the expense of an artificial apparatus, and, in consequence, the remaining half of the jaw has drifted to the median line somewhat. She is, however, able to chew food and is in perfect health, with no suggestion of recurrence at this date, fifteen months after the operation.

These are the only cases of disarticulation of the jaw from within the mouth known to the writer. In 1845, the late Dr. J. Marion Sims, in Montgomery, Alabama, in a case of osteo-sarcoma of the lower jaw,

divided this bone through the ramus with a chain-saw and removed the remaining section of the lower jaw from within the mouth without external mutilation. In the *American Journal of the Medical Sciences*, October, 1847, he says: "There are several considerations to recommend this operation in preference to the usual one with its extensive incisions. (1.) There is no external mutilation. (2.) As the third branch of the fifth pair of nerves was divided at the outset of the operation, its subsequent stages were comparatively free from pain. (3.) As no important blood vessels are cut, no ligatures are required. (4.) There is no trouble with the after-treatment. (5.) It is just as easy of performance as the old operation."

Fig. 2.—Left Half of Lower Jaw. Disarticulation from within the Mouth and without External Incision.

The operation is not difficult and is perfectly safe in proper hands, and cannot but be compared favorably with the procedures which require either incision outward through the cheek from the angle of the mouth, or down the median line of the chin to which is added an incision along the border of the lower jaw.

PERSONAL EXPERIENCE IN HERNIA OF THE BLADDER, WITH TABLE OF CASES.

By C. L. GIBSON, M.D.,

NEW YORK,

ATTENDING SURGEON TO ST. LUKE'S HOSPITAL AND TO THE WORKHOUSE AND ALMSHOUSE HOSPITALS.

Hernial protrusion of the bladder through the inguinal and femoral openings has been recognized as remotely as 1520 (Verdier). It has remained until recent years chiefly an anatomical curiosity. The modern methods of operation for radical cure of hernia require a more extensive dissection, which has resulted in the observation of a comparatively greater number of herniæ of the bladder. Clinically these herniæ may be divided into two classes—those frankly engaged in the hernial orifices, and those due to traction of the bladder into these orifices during the course of the operation. To the latter the term "operative cystocele" has been given. Both varieties are important, and their possible occurrence should at the present time never be absent from the operator's mind.

The limits of this paper will allow of but little general consideration of the subject. The literature has been recently so enriched by valuable papers in 1895 by Curtis, Fenger, Jaboulay and Villard, Salistcheff: in 1896 by Imbert and monographs in French and Italian—that in the absence of new views as to the origin or treatment of this condition a lengthy consideration would consist simply in reiteration of previous publications. This part of my paper will be confined to the report of clinical cases observed by myself, merely touching on the prominent features which they illustrated. In a second part I have endeavored to bring the literature of the subject up to date, having added forty-five cases to the fifty-eight reported by Curtis, a total of one hundred and three cases, which furnish some interesting statistical deductions.

My own experience of hernia of the bladder comprises four cases seen within a period of twelve months; twice in my own practice, twice while assisting colleagues. Two were inguinal (both in males), two were femoral (both in females). The bladder was opened twice; one inguinal, one femoral.

Case I.—As regards the first case, in June, 1895, I do not feel that I have the privilege of more than alluding to it. I only mention it to show the fact of my experience. It was in an inguinal hernia and was readily recognized by the surgeon whom I was assisting.

Case II.—M. S——, woman, fifty years old, admitted to St. Luke's Hospital, August 18, 1895, with strangulated right femoral hernia of ten days' duration. Condition very bad: pronounced sepsis. Immediate herniotomy. The sac contained a mass of gangrenous omentum: the ring was enlarged to allow a sufficient margin of healthy omentum to be pulled down and resected. With the omentum came a pouch-like knuckle of a hollow organ covered by peritoneum, which could be made to protrude only a slight distance. It was certainly not intestine, large or small, and it had every appearance of the bladder and was considered to be such: but the patient's desperate condition did not warrant me in wasting any time in further means of identification. Though but little shocked, the patient succumbed within twenty-four hours to her pre-existing sepsis. There was no post-mortem. I have absolutely no doubt as to the correctness of diagnosis in this case of intraperitoneal vesical hernia.

Case III. was observed while I was assisting in an operation in the practice of Dr. Robert F. Weir, to whom I am much indebted for permission to report the case. Miss B——, aged thirty-two years, had left femoral hernia of many years' standing. She was subject to chronic nephritis with occasional acute manifestations and hæmaturia. Operation for radical cure, December 27, 1895. The hernial sac was exposed, ligated at the highest part of the neck, and the distal portion cut away. A second structure then appeared in the inner angle of the wound. Supposing it to be a second sac, it was incised, whereupon urine came out. The identity of the bladder was further established by digital exploration, and, the incision being clearly in the extraperitoneal portion of the viscus, the opening was closed with a double row of catgut sutures and the bladder returned, protected by a strip of iodoform gauze. The rest of the wound was left open. A catheter was placed in the bladder for five days. The result was absolutely uneventful, the healing of the bladder being complete by primary union, and at the present writing the patient has remained absolutely free from vesical disturbances. No recurrence of the hernia or of the hæmaturia.

Case IV.—A man of fifty odd years. Operation in Almshouse Hospital, April, 1896, for radical cure of right inguinal hernia of long standing. The sac was buried in a mass of fat, which often accompanies old herniæ and to which the term lipocele of the cord is applied by French authors. It was necessary to cut through this very carefully till the sac could be reached. The latter was freed of all its adhesions till the neck was clearly defined, when it was ligated, cut off, and the stump returned into the abdomen. The fatty mass above mentioned, which had been torn off of the sac, still had to be dealt with before the deep sutures could be applied by Bassini's method. After careful examination it was ligated and cut away. On examination of the attached cut surface, a minute fragment of mucous membrane was seen. Removing the ligature, I discovered that this fat contained a thin

finger-like diverticulum of the bladder, which I had snipped off. The wound admitted a finger. It was wholly extraperitoneal. It was closed with a double row of silk sutures not involving the mucous membrane, and returned to its normal position protected by gauze packing. The hernial wound was packed. No catheter was employed. At first the bladder remained tight, but a minute sinus developed after a few days following unnecessarily vigorous probing. It was, however, only temporary. Since leaving the hospital the patient has been lost to observation.

In these two cases in which the bladder was wounded the conditions were those which furnish examples of most of the lesions recorded, namely, when the bladder is mistaken for a second sac or a reduplication of the peritoneum, and when a portion of the bladder is drawn out by the fat adhering to or surrounding it. This latter condition is one which makes its recognition occasionally very difficult. From my own experience in the first three cases I have had the possibility of lesion of the bladder ever present, and in several difficult cases similar to the last recorded had introduced a sound into the bladder to make sure of its absence. To this watchfulness I may attribute my discovery of the lesion, for at first sight a minute piece of mucous membrane rendered anæmic by a ligature and buried in a mass of fat might well be overlooked, with serious or fatal results.

The mechanism of this form is, however, quite simple. The extraperitoneal portion of the bladder behind the pubis is continuous with the rest of the preperitoneal fat, and when dragged down in the course of hernial descent draws out the adherent bladder with it, thus forming a cone whose interior contains that organ.

While the above represent most of the difficulties, there is another rare condition which may give rise to great trouble. In this the bladder lies in such a prominent position that it is mistaken for the hernial sac, or may represent all the hernia that exists—a hernia of the bladder in the strictest sense. Such dispositions are almost sure to deceive an operator unless the conditions are particularly favorable. In such cases there is generally no drawing out and thinning of the muscular wall, and the unusual thickness of the supposed sac may put the operator on his guard. My colleague, Dr. P. R. Bolton, of New York City, has been so kind as to allow me to record such an illustrative case.

The patient was a man, aged fifty-three years, with double direct inguinal hernia. Operation, July, 1896, for radical cure. On the left side the bladder lay directly exposed after removal of the superficial coverings. It was opened on the supposition that it was the proper hernial sac. The vesical wound was closed with catgut sutures. No hernial sac proper having been found, the condition was considered to present a true hernia of the bladder. The wound was packed with gauze. Patient died three days later and the post-mortem established the following facts: On the left side the bladder wound had given way, and although it was situated extraperitoneally urine had entered the peritoneal cavity by finding its way through a minute rudimentary hernial sac, in close apposition to the bladder, which had been opened simultaneously with that organ, and, not being recognizable, had not been sutured. The hernial portion of the bladder was of normal thickness. Examination of the right inguinal region showed the presence of a finger-like vesical diverticulum (in this case of normal thickness) through the conjoined tendon and the external ring, accompanied by a small hernial sac.

It should therefore be firmly impressed on the operator: 1st. That when an ordinary sac has been exposed and opened, anything resembling another sac should be looked upon with the suspicion that it may be the bladder, and should be approached as such until its identity with that structure is clearly disproved by all the means of recognition at our command. And further let it be remembered that exploring with a sound, distention with air or fluid, will sometimes apparently fail to establish the connection of a given structure with the bladder, and lead the operator to open this organ in spite of all the precautions taken. Several such cases have been recorded. 2d. All fatty material in the neighborhood of a hernial sac, especially on its inner posterior aspect, should be treated as if a portion of the bladder was hidden within it and should never be cut away till the absence of anything but fat has been demonstrated.

While the recorded cases of lesion of the bladder are very few, it is my belief that the accident is fairly common. I was so impressed with my own experience in encountering the bladder twice within a few months during the course of less than two dozen operations for hernia that it seems an obvious duty to bring up this subject again, although the admirable paper of Curtis in the *Annals of Surgery* has already fully covered the ground.

A perusal of this article, if they are not already familiar with its contents, is earnestly recommended to those who are doing operations for hernia.

The following observations are derived from combining Curtis' cases (58) and those collected in my table (45), a total of 103. These are divided into: Bladder wounded during operation, 67; bladder reduced without injury, 36.

Sex and anatomical variety of hernia: 76 cases were observed in the male, 23 in the female sex: 77 herniæ were of the inguinal variety, namely, 70 males, 7 females; 22 herniæ were of the femoral variety, namely, 6 males, 16 females.

The large number of femoral herniæ containing bladder is interesting in reference to Laidy's[18] observation in his paper in reporting such a condition, "that to the best of his knowledge his case is the first on record of the presence of the bladder in femoral hernia."

Age, under twenty-five years, 6 cases; twenty-five to fifty years, 35 cases: fifty and over, 52 cases. It is well to bear this proportion in mind, that more than half of the cases were encountered in subjects over fifty years of age. Wyeth's case, two and a half years, is the youngest so far observed.

The bladder was found to be present: intraperitoneal, 7; extraperitoneal, 73; intraperitoneal and extraperitoneal, 18. As previously pointed out, the intraperitoneal form continues to be the rarest observed. When it was not clear whether the bladder presented itself as the intraperitoneal and extraperitoneal varieties combined, and there was evidence that some portion of it was extraperitoneal, the case has been classified under the extraperitoneal variety.

The bladder was wounded under the following conditions: Mistaken for the hernial sac, 13; mistaken for a second hernial sac, 10: mistaken for other structures, 15; not seen till injured, 12; recognized but accidentally injured, 2. The "other structures," were for the most part accumulations of fat covering the bladder and continuous with the so-called lipoma of the cord.

The total mortality was 19 deaths in 64 cases, thirty per cent. This percentage must be analyzed in order to arrive at an approximate estimate of the mortality due to the vesical lesion. Curtis says of the 11 fatal cases tabulated by him: "In only 8 cases at the most can it be said that the vesical wound was even indirectly the cause of death." Of the 8 fatal cases contained in my tables I can eliminate the following

TABLE I.

WOUNDS OF THE BLADDER IN OPERATIONS FOR HERNIA.

No.	Operation and Date of Operation	Patient: Sex	Patient: Age	Hernia: Region	Hernia: Condition	Hernia: Other Hernia Complicating	Hernia: Variety	Bladder Wound Recognized	Bladder Mistaken for	Treatment: Bladder Wound	Treatment: Hernial Opening	Treatment: External Wound	Catheter a Demeure	Result: Bladder	Result: Duration of Sinus	Result: Recovery or Death	Time and Cause of Death	Size of Vesical Wound	Remarks

* The numbers indicate the bibliographical reference.

as dependent on conditions other than the bladder wound:

Reference	Cause of death	Time of death.
Demoulin (20).	Pulmonary congestion.	4 days.
Tuttle (21).	Acute nephritis.	2 months.
Salistcheff (10).	Purulent peritonitis after severe strangulation. Autopsy, bladder wound irreproachable.	2 days.

If then these 11 cases are deducted, we have a mortality of 12½ per cent., which is probably a fair estimate.

The following table of the mortality, according to the treatment, may be of some value:

	No. of Cases.	Deaths
Bladder sutured, no catheter à demeure (or none mentioned)	20	5
Bladder sutured and catheter à demeure	18	6
" " treated open (in the wound)	10	4
" " ligated or not treated	10	4

While the above table is based on too indefinite data to furnish clear indications for treatment, it fails to give any support to the treatment by the catheter à demeure. In certain cases the use of the catheter has been attended by very bad results. It might be well to limit the use of the catheter in general to the intraperitoneal variety of bladder wounds. In the other forms, if the bladder has been carefully sutured with a tier suture (preferably silk) the best results will probably follow the insertion of gauze packing (iodoform gauze should be avoided in elderly or nephritic subjects) at the site of the wound, application of provisional sutures, and leaving the wound open until the attitude of the bladder lesion has become apparent.

As regards the union of the bladder after suture, with reference to the use of the catheter, we find: Suture of bladder and catheter à demeure, 17 cases: sinus in 5, or 29 per cent. Suture of bladder, no catheter à demeure, 14 cases: sinus in 3, or 21 per cent. This table must be judged on its merits. It seems again to belittle the value of the permanent catheter.

Besides my indebtedness to the gentlemen previously mentioned, I must express my great appreciation of the kindness of Dr. J. P. Tuttle and Dr. J. A. Blake in allowing me to include two of their cases in my tables.

CONDITIONS WHICH MAY SIMULATE ORGANIC OBSTRUCTION OF THE LARGE INTESTINE.

BY THOMAS H. MANLEY, M.D.,

NEW YORK,

PROFESSOR OF SURGERY AT THE NEW YORK SCHOOL OF CLINICAL MEDICINE.

WITHIN the past few years a number of cases of anorectal disease have come under my care, both for treatment and in consultation, in which rectal obstruction, with or without incontinence, was the dominant symptom. But the most interesting cases, in which the symptoms were most accentuated, were those in which a stricture or new growth had been suspected, in consequence of painful or difficult defecation, yet in which on a systematic and searching examination no adventitious formations or strictures could be detected.

In searching through the annals of surgical literature, it was obvious that many of our most eminent authorities in past ages, and especially in this century, have given this subject of differentiation in diagnosis their most serious attention. Nevertheless, in current medical publications but little appears on this highly important topic. In this present instance only those obstructions of a colic or rectal origin will be considered, as these are most often of a non-inflammatory type or dependent on mechanical causes.

Anatomical and Pathological Considerations.—Inasmuch as the present study of intestinal stenosis is limited to the colon and its terminus, it follows that in order to comprehend the pathological conditions met with in this segment of the alimentary canal a brief review of construction and functions is necessary, because in many important and vital particulars we shall find here the anatomical elements and physiological phenomena quite characteristic and unique; and besides, a brief recapitulation of them will aid in

[1] Read at the annual meeting of the Mississippi Valley Medical Association, September 16, 1896, St. Paul, Minn.

the better understanding of diseased processes by all, no matter how conversant some may be with the normal anatomy of the parts under consideration.

We constantly read of "fæcal leakage, fæcal extravasation or admixture," after an injury to any part of the intestinal tract. But this is an error, as in health fæces proper are only found after the digested aliment has passed into the colic receptacle, which serves the purpose of a reservoir, similar in function to the bladder, to discharge its contents in obedience to the demands of nature as occasion requires. The caput coli begins as a large, flat, sacculated pouch, commonly embedded on its posterior surface in the loose connective tissues of the iliac fascia. The remainder of the colon is sacculated and gathered up into convoluted folds, by dense, broad, longitudinal bands. The ascending colon has no mesentery, but as it arches under the liver its transverse segment is gathered up by the gastro-colic omentum, until it takes another curve at its splenic arch, where the descending colon is fixed against the lateral abdominal wall; and when the crest of the ilium is reached the sigmoid bend begins. This segment has a mesentery of varying length, and ends where the rectum begins. The latter, in the male, is the only tubular structure of very great size passing out through the perineum. In the female, the relations of the vagina and rectum are so important, from a surgical standpoint, that a lengthy chapter might be written on them with great advantage, though only a short reference can be made here. Taking the large intestine as a whole, from the ileo-cæcal valve, where it begins, to the sphincter ani, where it ends, it strikes one as a needlessly complicated and worse than useless structure, which might be substituted by another which would equally well supply its purposes as a mere receptacle, without being, as it is from infancy onward, a constant source of danger and very frequently a menace to life itself: for it will be remembered that this pouch subserves no function essential to life, being restricted in this respect to receiving, storing, and discharging fæces. The movement of the fæces through the colon is languid, and is probably aided as much by respiratory action and gravity by as its own muscular development, which is very scanty and irregularly formed.

We note a wide distinction between the glandular layers of the small and large intestines. In the latter we encounter an excess of lymphoid stroma, with a diminution in the number and capacity of the glandular elements. Notwithstanding this, however, the internal surface of the colon, unlike that of the bladder, possesses great absorbing powers; *e.g.*, nearly any of the most lethal non-corrosive alkaloids may be injected in solution with impunity and retained in the bladder: while if the same substances in the same form were injected into the rectum, they would almost at once produce toxic symptoms. This singular difference in the resorbing properties of these two excretory receptacles is most striking, and it is remarkably reversed when we view it from a clinical standpoint; when we recall the prompt constitutional disturbances serious impediment to urinary discharge will provoke, and, *per contra*, the impunity with which the system will for weeks, and sometimes even months, tolerate enormous fæcal accumulations in the large intestine. Vesical distention appears to give rise only to uræmic symptoms and constitutional infection when inflammatory changes in the mucosa have been produced. But in cases of fæcal infection of the rectum, provided its development has been gradual, it may persist over a very long period before such grave constitutional disturbances arise as call for active relief.

Peculiarities of the Movement of the Residuary Elements of Alimentation in the Colon. The movement of the semifluid aliment in the intestine is one of ceaseless activity, although it varies in degree in different situations and at various intervals of digestion. If we quickly open the peritoneal cavity of an animal, we may witness the slow, regular, peristaltic wave, the vermicular movement of the intestine, more active in some coils than in others. With the palm of the hand laid flat over the nude surface of the bowel, we are distinctly sensible of a double motion: first, we feel the alternate contraction and expansion of the ring muscle, with a rising and falling movement induced by a contraction of the longitudinal muscle fibres. The small intestine, after it clears the retroperitoneal tissues of the duodenum, is free and unfettered in all its movements: but not so with the large intestine, which is in its greater part a fixed organ, and in structure made up largely of strong bands of fibrous connective tissue, and passive in motion. With this segment of the alimentary canal exposed, no peristalsis is present. But if we seize the colon in the hand for a moment, we will observe that its walls have exhaled a distinct fæcal odor. The phenomenon would go to show that the diffusion of sulphuretted hydrogen gas through the colon is probably constant, and is certainly innocuous. The fæces, as they pass through the colon, must clear three angles and as many curves. The first and most pronounced is the ileo-colic. This is fairly constant in the human being, although we sometimes find at this site a persistence of the fœtal type, or that of the rodent, wherein the fusion of the large and small intestine is in the direction of the long axis of the bowel. At this point the first impediment to the intestinal contents is encountered. Here they are projected beyond the trap-door valves and lodged in the colic reservoir: and at this point, exclusive of the rectum, fæcal impaction most commonly occurs. At this point the fæces are sent directly inward, then down and into the base of the cæcum, there to make a counter detour upward, against gravity, and pass the hepatic flexure.

The position and direction of the transverse colon are subject to many variations, some of which may give rise to serious consequences, as has been plainly pointed out in a recent able contribution of Dr. Theodore W. McGraw.[1]

The transverse colon lies on the anterior surface of the small intestine, its horizontal segment, through its relations and connection with the stomach, being liable to constant changes, with the distention of this organ. As the stomach descends, the transverse colon is arched downward, again regaining its normal direction on the evacuation of the contents of the stomach. Sometimes, in consequence of various pathological conditions, especially those favoring displacement of the kidney or in umbilical hernia, not only do we find an accessory arch, but such acute bending of the hepatic and splenic flexures as will surely lead to mechanical constipation, indigestion, or dyspepsia.

The colic spiral—the sigmoid flexure—is provided with a free mesentery, and is capable of enormous dilatation. This lies behind the small intestine and lodges the fæces, prior to evacuation. After we pass this double bend, we come to the rectum, the musculomembranous terminus of the alimentary canal.

Irregularities of Development and Congenital Defects.—The experienced surgeon understands well the difficulties which may present themselves during the course of an operation on any region within the peritoneal cavity, from atypical development and the disordered relations of the viscera, so often met with after the abdomen is opened. McGraw well emphasizes this in connection with the anatomy and surgery of the colon, and Jacobi has called attention to the frequency of obstinate constipation, and even serious fæcal ob-

[1] "Surgery of the Large Intestine," Annals of Surgery, August, 1896.

struction, in consequence of a preternaturally elongated mesentery of the sigmoid in the infant.

Since the iliac operation first became a procedure *au courant* for pathological lesions of the caput coli and appendix, it has been my custom, when opportunities to make autopsies have permitted, to examine carefully the entire colic tract, especially at its origin. In the course of this investigation, I have been struck with the great diversity found in the proportional size of the large gut and its relations to other organs. In one subject, a woman, the colon was found no larger than the small intestine; in other instances there was practically no diverticulum at the cæcal end, and the ilea in others were found to join the colon in the most diverse directions. The most variable of all structures was the meso-colon, sometimes so long as to permit the cæcal end to make excursions in various directions, far from the side where it is most commonly lodged.

The gastro-colic folds of the omentum greatly vary in density and in their elongation tendencies, in some few instances being readily drawn down in its centre as far as the pubis. The most constantly fixed portion of the colic tract was found to be the descending colon.

The sigmoid bend in the female is capable of great distention, and in this sex its long mesentery allows of a very wide latitude of motion, probably in order to fill physiological demands. The rectum is found the most regularly formed segment of the large intestine, although more generally influenced by pathological conditions in neighboring organs and structures than any other.

Influence of Sex and Physiological Conditions.—We observe the widest differences of relations of organs along the ano-rectal tract in the male and female. In the former the base of the bladder is supported by a septum of loose connective tissue, immediately below which is the prostate, lying between the urethra and rectum. The ampulla or rectal pouch rests in a bed of loose adipose tissue, which is capable of great distention; sometimes, in cases of impaction, occupying nearly the entire hollow of the pelvis.

In the female, we note a wide departure in both the anatomical relations and the functions of the adjacent organs. In her the vulva, the vagina, and the uterus widely separate the rectum from the entire urinary apparatus; although in pathological conditions of either, the genito-urinary and rectal organs reciprocally act on each other. The rectum is always encroached on by the distended bladder, and, *vice versa*, the loaded rectal ampulla advances forward and bears heavily on it, in such a manner, in aggravated cases, as to produce polyuria or troublesome rectal tenesmus. In the pregnant state, during the earlier stages, while the uterus is yet in the pelvis, the rectum and vascular apparatus are steadily compressed; as this state, however, is only intermittent, and as the healthy rectum in young women is generally empty, no harm results, although constipation is one of the earlier symptoms of the parturient state.

Clinical History of Intestinal Obstruction in General.—To enter on anything like a detailed description of the vast number of pathological conditions which lead to occlusion of any part of the intestinal canal would be a large undertaking, far beyond what is intended here; still, it cannot be entirely passed over, as to that part of the intestinal path above the large bowel while endeavoring to set forth the symptomatology of those obstructions limited to the elongated fæcal pouch.

Intestinal obstruction may occur at any stage of life, but is by far the most common after middle life; after degenerative changes commence in the vascular, nervous, and muscular systems; at that stage in life when the consequences of defects in development begin to declare themselves, hereditary tendencies, changes in the organs and the susceptibility of the tissues to the invasion of malignant disease are evident.

Obstruction of the lumen of the bowel is, in general, dependent on influences of two orders—one, intrinsic, restricted to the intestinal wall and its immediate investments; and the other, extrinsic, in which obturation, partial or complete, results from pressure transmitted from other organs or structures; to which might be added impaction from foreign or autogenous bodies in the lumen of the bowel.

Dangers to Life in Intestinal Obstruction.—The dangers to life in intestinal obstruction depend on many circumstances, the most important of which are (*a*) its situation, (*b*) its acuteness, and (*c*) its completeness. That dreadful *ensemble* of symptoms which we witness in obstruction of the small intestine will generally be absent when the larger is choked up or closed. Obstruction of the large intestine is very seldom acute or complete, except in very advanced malignant disease or in hernia. It cannot be said that life is ever suddenly jeopardized by occlusion of the large intestine, except when it is forced out of the abdomen by a hernial extrusion; and even here, in my own experience, in those cases of descent of the cæcum or the sigmoid, in strangulated hernia, the extent of shock or collapse is not by any means so marked as when the small intestine is nipped in the portals of escape.

From the above observations, it becomes at once apparent that emergency operations on the large intestine, for sudden occlusion within the abdomen, are rarely if ever called for. This being conceded, it is obvious that, when any part of the sewer vent of alimentation becomes obstructed from any cause whatever, sufficient time is permitted the operator to make all necessary preparations to insure the greatest degrees of success from surgical intervention.

Although we are seldom forced to open the large intestine in any of its areas under pressure, there is no segment of the alimentary canal so often tapped for mechanical obstructions, none with greater impunity or greater advantage to the afflicted. Assimilation of the aliment is ended when the injecta reach the cæcal portal, and from this point around the colic circle the greater part of the intestine is extraperitoneal and in close contact with no highly vascularized areas.

Morbid Anatomy of Obstruction in the Large Intestine.—For the purpose of simplifying the study of the morbid anatomy, we may commence with advantage at the ano-rectal outlet, as this is by all odds the most frequent seat of obstruction, through fæcal impaction, as well as obliteration of the emunctory by the manifold pathological changes in the mucous and submucous tissues, anywhere from the anal verge to the peritoneal investment of the rectum above.

Hemorrhoidal Degeneration.—Pathological changes in the superficial and deep veins at the anorectal junction lay the foundation of the vast majority of those manifold diseased conditions known by the laity as "piles," or hemorrhoids of numerous types. Now, in not a few of these cases of a chronic character, trophic changes extend up the wall of the bowel, reducing its expulsive power, so that the alvine discharges are imperfectly dislodged or with such difficulty as to cause one to suspect stricture. This surmise is strengthened by the ribbon-like moulding of the evacuations. All these signs are apparent in consequence of the pronounced stasis in the ano-rectal veins, an interstitial inflammation, and hyperplasia leading to a falling in of all the rectal walls: a condition aggravated by violent straining at stool when the discharges are at all solid.

Pathologically the condition is quite the opposite of undue contraction or submucous fibrous induration, as impediment and resistance come from relaxation, want of tissue, and tendency to prolapse.

Rectal Dilatation Consecutive to Enervation and Atrophic Changes in the Rectal Walls as a Predisposing Factor in Fæcal Impaction in the Ampulla.—The levator ani in the male chiefly serves the purpose of powerfully aiding in the expulsion of the alvine mass, after it has entered the rectal pouch. But in the female this muscle exercises more complex functions, being not only concerned in defecation, but also contributing largely as a support to the perineal body, thereby indirectly supporting the vagina, the uterus, and the bladder. This muscle often sustains serious damage in tedious or difficult labors, permitting thereafter a tendency to uterine displacement and a prolapse forward on the weakened anterior wall of the rectum.

The upright attitude of the human body, involving a strain on the venous system in consequence of the movement of the blood against gravity, favors premature degenerative changes in the vessels of the lower extremities and the rectum. Therefore, varix of the hemorrhoidal vessels in various degrees appears, and when aggravated becomes infected, inflames, or ulcerates. In aggravated chronic cases, a low grade of inflammation is propagated through the walls of the bowel into the muscular tissue of the levator ani and sphincter ani muscles.

Now that the integrity of the rectal support has been undermined and atrophic changes are manifest, disturbance of function soon follows. This presents itself by two opposite conditions. One is a hyperæsthesia, with a weakening of the external sphincter and prolapse of the pre-anal folds of the rectal mucous membranes during and after defecation. In the other pathological state, the normal sensation of the rectal mucous membrane is annulled; and though the external sphincter remains well closed, the levator ani has diminished in its contractile power and permits of enormous insensible dilatation. With this latter phase alone of trophic change are we now concerned. It is well to remember, however, that rectal enervation, atrophy, and impaction are often dependent on other pathological conditions than those enumerated, the most conspicuous being degenerative, as in the anæsthesia of old age, in locomotor ataxia, in dementia, or any pathological state of the brain or spinal cord which perverts or diminishes the conducting powers of the sensory nerves. The patient, on defecating, fails thoroughly to empty the rectum; some scybala remain, concretions form, and in time massive enteroliths, fæcal calculi, solidly fill the hollow of the pelvis. These fæcal deposits in some individuals seem to undergo petrifaction, and in certain instances it seems inexplicable with what impunity they are retained without giving rise to ulceration or sloughing, the acquired tolerance of the tissues permitting their insensible lodgment over periods of months and years. How, also, with those large bowlders jammed solidly into the rectal ampulla, the fæces can filter down by them, seems quite incomprehensible.

In one case last year, my patient, an aged gentleman, the father of a physician, declared to me that he had unconsciously carried his enormous enterolith for fourteen years. This, he said, he was positive of, because since that time an evacuation was impossible, unless his valet gave him a large soap enema, which was done every morning. In this case, after detaching the mass, I undertook to deliver it with an obstetric forceps; but as the external sphincter would not yield amply for it to pass through, I had to split it with an osteotome and displace it in sections. It had the shape and outline of a medium-sized cannon ball. After this was dislodged, several other globular bodies, varying in size from the fist to a pigeon's egg, were brought through the anus.

Enlarged Prostate.—It is my conviction that prostatic hypertrophy, when it engages the posterior half of the lateral lobes, is a prolific source of fæcal stasis or impaction in elderly men. It stands out in the lumen of the gut in such a manner that as the fæces descend their course is deflected, so that what passes must make its way through an irregularly formed chink, in consequence of which a considerable residue is left behind, to form the nidus of a later concretion.

The female rectum, in the child-bearing woman, in the weakly and those advanced in years, is greatly exposed to influences of an extrinsic order which positively interfere with the free movement of the rectal contents. In the most aggravated cases, a condition clinically and pathologically analogous to those types of hernia which sometimes obtain in the male exist, in which the tendency to visceral prolapse is so great that no description of surgical procedure will permanently cure nor apparatus entirely control.

The anterior wall of the rectum, having lost the contractile aid of the wasted levator ani, is devoid of support and falls forward into the vagina; the recto-vesical fascia allows of a descent of the base of the bladder; and, what is most common, the uterine ligaments stretch, retroversion follows, and the uterus falls back and downward, steadily maintaining an uninterrupted pressure against the rectum.

How many women thus afflicted are fruitlessly treated for constipation with laxatives? And how many are there, with predisposing tendencies to hernia, who complete its evolution by the straining at stool necessitated by this disordered position of the pelvic organs? This tendency to procidentia in the female, although by no means infrequent, is not one of those "conditions which may simulate obstruction of the rectum" in an aggravated degree, although it is, nevertheless, a source of serious apprehension in some cases, through the discomfort it may give rise to, and especially when an error is made in diagnosis and the medical attendant mistakes the ectopic uterus for a morbid growth, as has occurred in two cases coming under my own immediate notice. One case was in a married lady, coming from Utah for an operation for the removal of a tumor of the rectum that did not exist. The other was a young, unmarried woman, who had suffered from backache and straining at stool. She was brought to me by her physician, who wished to have arrangements made for an operation. Comfortably fitting pessaries promptly relieved both cases.

It is well known that the sigmoid flexure, particularly in women, may undergo, under various circumstances, enormous dilatation. Surgical literature abounds with the records of such cases. The latest and fullest contribution on this subject appeared in *La Suisse Romande*, in May, 1894, by Reverdin. In one case there enumerated, although obstruction was not complete, the mass attained to such proportions that a new growth was suspected and the abdomen opened. An enormous fæcal mass was removed from the sigmoid, with fatal results. Next to the rectum the sigmoid flexure is in women the most common seat of impaction of an aggravated description; although, probably, in most instances this is consecutive to stagnation lower down.

Hernia.—Of all the causes of acute and complete intestinal obstruction, hernial protrusion occupies a foremost rank. How many there are who have a "stoppage of the bowels," and in vain, by cathartics and enemata, the intestinal passage is forced; when, alas! often too late, a rupture is discovered. A hernial extrusion has painlessly and unconsciously come down and become strangulated, or a small undiscov-

ered one has been suddenly caught in the portal of escape. But strangulation of the large intestine is not common. It is said to occur in about one in every twenty cases, according to Astley Cooper. In my own operations for strangulation, I have on four occasions found the cæcum in the sac. In a femoral hernia of a woman, the sigmoid flexure was discovered; while in several umbilical herniæ—twice in the strangulated and four times in operation for radical cure of the reducible hernia—the transverse colon has been found.

Quite a few cases have come under my observation of intermittent obstruction of the colon, from the temporary incarceration of a knuckle of the colon, in both the reducible and irreducible herniæ of various anatomical types. This last summer an instance came to my knowledge illustrating this. The patient, a young man from Virginia, was brought to me by his surgeon for examination and advice. He had some time previously been treated with rectal bougies for rectal stricture, but without benefit. I could detect no evidence of such a lesion on the most careful examination. But he had an inguinal hernia, which could not be well retained with a truss. When this came down and became tumefied, his evacuation ceased and the distress was great. When it was reduced, he was easy and comfortable. I advised an operation, with a view to detaching the colon, which evidently had contracted adhesions and led to kinking when displaced; besides to attempt a radical cure of the hernia at the same time.

Neoplasms.—Tumors of an extrinsic origin seldom induce a dangerous stenosis of the large intestine. The economy provides a way of escape in most cases, by the property of the mesentery to elongate, and thus allow the gut to move out of the way of an encroaching growth. In sarcoma of the liver or kidney, leading sometimes to enormous enlargement and displacement, the colon makes an excursion out of reach of great pressure. The same is true of most new growths involving the uterus or ovaries; although in massive fibroids of uterine origin mechanical constipation is one of the most serious complications we have to deal with.

Cæcal Obstruction.—Independent of invagination of the cæcal end of the small intestine in infants and young children, we seldom encounter mechanical impediment at this site; and although fæcal impaction is not very unusual here, it is probably one of the most prolific causes of diseased appendices. This part of the alimentary canal is not so distensible as that nearer the anus, and is very prone to take on inflammation from trauma sustained from without and the effects of overdistention in impaction. Obstruction from the lodgment of foreign bodies or concretions carried down the small intestine seldom can occur in the caput coli, because anything that can clear the ileocæcal valve readily passes on through the colon.

The above briefly summarizes the principal pathologic causes, other than organic, which embarrass partially or completely the fæcal current on its way out of the body.

The Symptomatology and Diagnosis of Conditions which may Simulate Organic Obstruction of the Rectum.—The symptoms which attend rectal or colic obstruction may be grouped in the classes, local and constitutional.

Local Symptoms.—This class is the more numerous and less accentuated. The patient complains of being costive. Constipation is the rule. His motions are hard, or, if enemata are frequently given, the fluid discharges lead him to believe that the passages are loose. In most of these cases, in which the seat of impaction is in the rectal ampulla, the pressure resulting may give rise to pain in the back, lumbago, sciatica, or vesical weakening, rendering frequent urination necessary and producing a tendency to vesical leakage. On evacuation of the bowels, there usually remains a sense of fulness with rectal tenesmus. In nearly all cases we find an engorged, congested state of the hemorrhoidal veins, some of them being thrombosed, their bases fissured, and occasionally the smaller sacculated masses covered by a granular surface, prone to bleed on moderate irritation. In these cases "piles" are commonly complained of, and a moderate grade of proctitis is present.

The vesical symptoms vary in different individuals. In some the bladder in a large measure escapes severe pressure, by its fundus rising out of the pelvis; nevertheless, vesical complications are quite inevitable in protracted cases. The weight of the fæcal mass induces an irritation of the prostate and interferes with a thorough drainage of the bladder. The healthy rectum in the young or middle aged should be always empty, but in this class a residual mass of hard, desiccated fæces remains.

Acute obstruction of the large intestine is invariably consecutive to chronic impaction, dependent on an impediment culminating from within. The large intestine in the normal state is quite devoid of sensation, and even on great distention by either solids, liquids, or gases is quite insensible to pain, except when stoppage is complete or adjacent organs are being impinged on. When cæcal impaction occurs or the fæcal current is impeded, by a displacement of the colon in ventral or umbilical hernia, the patient is conscious of a sense of soreness over the site of stasis, with occasional attacks of severe colicky pains.

Sigmoid and rectal impaction in the female, unless caution be observed, is liable to be confounded with various genito-urinary disorders. Pathological conditions of the genital organs of women are so common that unless we scrutinize our cases carefully we may confound them with rectal disorders. And constipation is such a common habit with some women that when medical aid is summoned, unless one is closely questioned, she may neglect to speak of the stools entirely, and thus lead to mistaken conclusions on the part of the physician. A case of this description came under my care five years ago.

The woman had been suffering from the most intense abdominal pain for some days before, and had been so freely plied with morphine as to be well narcotized when I saw her. On examination it was elicited that she had had no evacuation of the bowels for two weeks, nor passage of water for more than twenty-four hours. An unsuspected, undiscovered, large scirrhous mass was found, which now wedged the rectum so tightly as to prevent the passage of anything outward; and fæcal distention so enormously pressed forward the whole large intestine that its outline could be distinctly defined through her attenuated abdominal walls. There can be scarcely a question that a considerable number of supposed ovarian and uterine maladies are but reflex symptoms, or dependent on distortion or compression of the pelvic organs by sigmoid or rectal compression.

Hernia, when involving the large intestine, may give rise to unequivocal symptoms of obstruction, their degree and intensity varying according to the anatomical site of the part involved. When the small intestine is the seat of strangulation, the symptoms are quite unequivocal; for this area of the alimentary canal is the centre of digestive activity, and is most abundantly supplied by the sympathetic system of nerves. But with the large intestine the manipulations of mechanical impediment are much more obscure and indefinite.

An instance of hernial occlusion of the transverse colon in the umbilical extrusion of a child of four years came under my care three years ago. The pa-

rents said that for nearly two weeks there had been no movement, when the navel swelling gradually enlarged and burst through the skin, the entire alvine mass escaping in this manner. In a section undertaken to close the fistulous opening, a spur of the colon was found engaged in the passage of escape. The interesting and important clinical feature in this case was that, during these two weeks, there had been no constitutional disturbance of any kind.

It is of great importance in all these cases of colic impaction coincident with hernia that we look closely for symptoms emanating from rupture, alone or as a complicating factor of obstruction.

The symptomatology of intussusception belongs to the surgery of infancy rather than to that of adults, and will be omitted. I have never met with a case of intussusception in the adult, nor are any such cases recorded in modern medical literature.

The Constitutional Disturbances attendant on impaction or complete obstruction of the large intestine, except when attributable to volvulus, ileus, or hernia, bear but little comparison with those witnessed in the upper segment of the intestinal tube. The onset is more chronic and the symptoms presented suggest autoinfection, absorption, and toxæmia rather than any violent disturbance of the nervous system. In non-organic impediment to the colon's contents, the causes in operation frequently are of long duration and do not seriously menace life, and therefore sudden profound systemic disturbance is an exceptional condition.

Diagnosis.—Differentiation in diagnosis in the various types of stenosis of the large intestine enables us not only to forecast events, but also to institute judicious treatment. A complete and detailed history of the case will throw much light on its probable character, although we must be guarded and not attach too much credence to certain of the patient's statements. For example, in some of the worst cases of impaction from rectal inertia, a patient may tell us that the passages are not only regular, but too free; in fact, that he cannot quite control them, a fairly safe sign that some description of mechanical obstruction exists. Nor can we rely on the statements regarding the completeness of an evacuation; for a patient may deceive himself and believe that he has emptied the rectum, while as yet a considerable residue remains behind. Our main reliance, then, must be on a physical examination. However repulsive this may seem, it should never be omitted in suspected cases; but it should be carried out methodically, with skill and deliberation. When hernia can be eliminated and when time permits it, it is well to begin by giving a mild purgative the day before. The patient should be placed on a firm table in good light.

The most common pathological state of the lower bowel leading to stenosis is malignant growth, generally of an epithelial type. If we can eliminate cancer in these cases, permanent means of relief are available in the majority. This dreadful malady works great havoc in the large intestine, as may be gathered from the latest statistics on this subject.

Sutton says that "ninety-eight per cent. of cancer of the bowel occurs in the large intestine, seventy-five per cent. in the rectum, ten per cent. in the sigmoid flexure, four per cent. in the splenic flexure, three per cent. in the hepatic flexure, two per cent. in the cæcum, and four per cent. in the intermediate parts." As Pilcher puts it, we may say that from six to eight per cent. of all carcinomata have their origin in the large intestine, the larger portion having their origin in the rectum or sigmoid flexure.[1]

Cancer of the large intestine has practically no symptomatology, until signs of either stenosis or hemorrhage appear, as this lesion here, as in other viscera, is quite devoid of pain in its earlier stages. Dysentery, ulceration, syphilis, or tuberculosis may each lead to a contraction of the intestinal lumen; but all of these have a fairly definite clinical history.

Mode of Examination.—We proceed to make our physical examination through two media: First, by the surface; and second, per rectum. In thin subjects we may derive valuable information by inspection, palpation, and percussion. Hernia may generally be readily detected when of fair volume, emerging through the ordinary portals; but when of diminutive volume, or appearing in unusual situations, as the obturator, pudendal, or other type, it may be readily overlooked, especially in fat subjects. Cæcal impaction may be recognized when of considerable volume, as may be that of any other area of the large intestine, except the sigmoid flexure, which, having a free mesentery and in the female being in close contact with the organs of generation, may be readily confounded with inflammatory or neoplastic diseases of them.

The sigmoid when greatly distended may, in some subjects not too fat, be readily mapped out by percussion. It is important in all these cases first to empty the bladder and determine the condition of contiguous organs. Below the sigmoid our examination is restricted to inspection and digital manipulation through the anus.

Anal Examinations may be made with the patient on the side or back. The range of examination here for the finger is limited, though by bimanual manipulation very much valuable information may be gathered. The rectum is the most common seat of all pathological conditions of the large intestine, and, fortunately, this pouch is the most readily explorable segment. In examinations of it we are dependent almost entirely on the sense of touch.

In the young healthy adult subject the rectum is quite empty, and the tip of the finger may be pressed up through it to a point just below the sacral prominence, or about the point where the peritoneum is reduplicated over it. After middle life, when degenerative changes set in, in both sexes notable alterations will be readily recognized in this part.

Hemorrhoidal disease, a pathological condition so common in man, has led to trophic changes of various degrees at the ano-rectal junction: in the male anteriorly we often find more or less enlargement of the prostate, and in women a backward inclination of the uterus. Besides, as age advances, the rectum has lost the power of complete expulsion of the fæces, and quantities of varying consistency will be found lodged therein. Except for lesions involving the mucous surfaces, the rectal speculum will afford us little aid in diagnosis.

Extensive dilatation of the sphincter ani is not required in mere digital examination of the rectum, as differential diagnosis must be reached entirely here by tactile sensation.

Rectal impaction from anal stenosis, paresis, or atony of the intestinal wall is without question a most prolific cause of many of the reflex neuroses, vesical irritation, etc. Many painful conditions of the female generative organs should be sought for by rectal examination, and relieved in every case that gives a history of chronic constipation. Many hastily assume that because a purgative promptly acts, there is no mechanical impediment in the lower bowel; but experience proves that though the fluid fæces make their way through, there often remain lodged in the large intestine large hardened scybala, to maintain an irritation and interfere with normal evacuations.

Conclusions.—Obstructions in the large intestine are of two kinds: viz., first, the active, acute, or complete; second, the passive, chronic, or incomplete.

[1] Dennis, "Surgery," vol. iv., p. 465.

The former are the most rare and dangerous, with few exceptions depending on hernia, paresis from inflammation, or occlusion by new growths of extrinsic origin. The latter derange the general health, though they seldom immediately imperil it. They are essentially dependent on habit, occupation, or senile changes; or occur secondarily in consequence of extrinsic influence.

They are more common in the female sex, in consequence of differences in the anatomy and functions of neighboring organs; and may give rise to such symptoms as may lead the unwary into suspecting uterine disorders.

By a methodical, systematic examination of cases of intestinal obstruction, we may generally be enabled to determine whether the large or small intestine is the seat of stenosis or occlusion, by certain well-defined symptoms; and when the large intestine is the seat of trouble, we may determine not only the area involved, but likewise whether such obstruction proceeds from causes of an extrinsic origin or from pressure conveyed through other sources; a practical knowledge of the etiology and clinical history of which will clear the way for safe and effective treatment.

Progress of Medical Science.

Relapsing Sore Tongue.—Mr. Jonathan Hutchinson recently observed a case of the above-named affection. There were large abraded patches upon the surface of the organ, and these resembled a severe attack of herpes. Herpes of the tongue occurred chiefly along the margin and tip; herpes of the tip was exceedingly common. Sometimes these attacks supervened with such frequency that the patients were scarcely ever free from them. The history of the present case was that the disease had persisted off and on for twenty years. At intervals the tongue would be quite sound, but after some months a relapse would occur. The present attack, which had lasted for four months, was the most severe which the patient could remember. On examination of her teeth, one tooth was seen in which an amalgam stopping had been used. Mr. Hutchinson here remarked that he entertained great prejudice against amalgam stoppings in teeth, especially in mouths which were sore. In such cases he always insisted upon the amalgam being removed and gold inserted in its place. Dentists, he stated, would not believe that any harm arose from amalgam stoppings, but he was satisfied that in certain conditions some chemic solution of the amalgam took place. Most often the tongue became sore opposite the tooth in which the amalgam was present. Moreover, he had often found that patients could tell by means of a slight metallic taste in their mouths which tooth it was in which the amalgam had been placed. Again, he had often seen cases of sore mouth in which all the symptoms had been relieved by replacing the amalgam with gold stopping. The pellicular condition of the patient's mouth was most interesting. In some respects the leucoplakia somewhat resembled that seen in smoker's tongue, but more inflammation was present than was usually observed in the latter condition. It was worthy of note that the filiform papillæ had disappeared over a large area. The patient, on being asked if any particular articles of diet caused irritation to her tongue, replied that anything sharp did so, and in this connection she instanced vinegar. She also avoided walnuts. Mr. Hutchinson was interested to find that she had herself discovered the irritating effect of walnuts. He pointed out that walnuts were especially harmful in these cases. The old, dry walnuts were possibly not much to be blamed in this connection, but the juice of the rind of the young moist walnuts was especially irritating. He had seen many cases of sore mouths arising from this cause. Again, such patients should avoid all effervescing waters, and sugar in combination with vegetable acids was very harmful. The remedy for these cases was arsenic.—*Medical Press.*

The Action of Fasting and of Meat and Vegetable Diets on the Duration of Elimination of Salts by the Kidneys.—The question of absorption and elimination of medicinal substances is one of the most important in therapeutics. It would be advantageous to know in what shape and manner the administered drugs are absorbed and later eliminated. The latest researches on the subject are those of Debogorie-Mokriewitsch, says the *Medical Review.* The author conducted his experiments with potassium iodide and sodium salicylate. The experiments were intended to determine the length of time of elimination by the kidneys of the two drugs, during a vegetable regimen, a flesh regimen, and during fasting. The experiments numbered one hundred and forty, and adult persons and dogs were the subjects of the investigations. The author gave the drugs to persons who were on a vegetable and animal diet respectively. He found that elimination was prolonged when the food was limited to vegetables. When he gave four grains of potassium iodide to the person on a vegetable diet he recognized the chemical reaction of the salt in the urine for fifty-one hours. The same amount was entirely eliminated in thirty-four hours by a person on a meat diet. The experiments with sodium salicylate gave the same results. Eight grains of the salt required twenty-seven hours for elimination under the vegetable regimen, while twenty-three hours was sufficient for the excretion under the meat diet. The experiments on dogs gave the same results, that the vegetable diet prolonged the time of elimination. The investigations conducted to determine the influence of fasting on elimination were interesting, and showed that the time of elimination was greatly prolonged. One grain of iodide of potassium was eliminated in twenty-six hours by a dog on a flesh diet, while the salt was detected for fifty hours in the urine of a fasting dog. Six grains of sodium salicylate were eliminated in twenty-nine hours by a dog fed on meat, while one from whom food was withheld required thirty-four hours for the complete excretion. The author drew the following conclusions from his experiments: 1. That there is a close relation between the time of elimination of medicinal substances and the quality and quantity of foods. 2. The length of elimination is shorter with a meat diet than with a vegetable diet. 3. An increase in alimentation with its subsequent increased renal activity hastens the elimination. 4. Fasting prolongs, to a great degree, the elimination.

A Case of Acromegaly with Goitre, and One with Exophthalmic Goitre.—Murray (*Edinburgh Medical Journal*, February, 1897, p. 170) has reported two interesting cases of acromegaly, one of which was attended by a large goitre and the other with exophthalmic goitre, pulmonary tuberculosis, and glycosuria. The one case occurred in an unmarried woman, thirty-seven years old, in whom the thyroid gland became enlarged at the age of twelve years, subsequently diminishing in size until it caused no inconvenience. Between twenty and twenty-five years of age, the patient was overworked as a teacher and suffered greatly at night from a dull aching pain in the left mastoid region. This pain gradually extended all over the head and became constant, while the thyroid gland again increased in size and became firmer in consistency. The pain in the head became so troublesome that the

patient was compelled to give up teaching at the age of twenty-five, and it persisted until the age of thirty-one. The patient complained of great loss of strength and energy. She presented the characteristic appearances of acromegaly, together with prominence of the eyes, narrowing of the palpebral fissure from drooping of the upper eyelid, enlargement of the thyroid gland, increased frequency of pulse, excessive perspiration, and symptoms and physical signs of pulmonary tuberculosis. Examination of the urine disclosed further the presence of sugar. A distinct fine tremor of the hands was visible when they were extended. A skiagraph of one of the hands showed the greater part of the enlargement to be due to an overgrowth of the soft tissues. The shafts of the phalanges were thickened, but the ends did not appear to be larger than normal. Neither the metacarpal bones nor the phalanges were increased in length. In the middle and terminal phalanges of each finger, the (proximal) epiphysis appeared separated from the shaft by a narrow line, indicating that complete osseous union had not taken place between the two. A skiagraph of the foot also showed an increase in the soft structures, but the bones exhibited no enlargement. The second case occurred in a woman, sixty-three years old, in whom the thyroid gland was noted to be enlarged following an attack of whooping-cough at the age of thirteen years. From this time the goitre gradually increased in size until the age of thirty. For four years there had been attacks of left facial spasm, at first occurring in paroxysms, but for two years being constant. The patient exhibited the characteristic appearances of acromegaly, and in addition had a cystic goitre arising from the isthmus of the thyroid gland, with also some enlargement of the lateral lobes of the gland.

Prophylaxis of the Infectious Diseases of Children.—Dr. A. G. Wollenmann says that the only successful prophylaxis for these diseases is the destruction of the germs. The principal thing is thoroughly to disinfect the surface of the entire body, where, generally, the most infectious matter is deposited. The skin must, at least thrice daily, be washed with potash soap. Ordinary potash soap is preferable to any other antiseptic soap, as the latter can in no way be applied in sufficiently concentrated form. The skin of children is very sensitive to antiseptics, and applying these three times a day may easily produce toxic symptoms. The surfaces of nose, mouth, and ears, as well as the face, must be thoroughly rubbed with soap and then washed in warm water. To wipe the parts, clean old linen should be used and then be burned. A mosquito net in tent shape may be put over the bed wherein the patient lies, to limit further dissemination of the infectious germs. On the netting, masses of these germs will adhere, hurled there through expiration and spasmodic cough. Bedclothes and clothing should be often changed. Sheets and clothing once used must be soaked in two-per-cent. carbolic-acid solution or in two-per-cent. chloride-of-calcium solution, for several hours in the sick-room. Later on, by washing and boiling, all germs will be destroyed. Absolutely nothing should be in the patient's room save the most necessary articles and utensils. The room must be kept perfectly clean, and should be thoroughly ventilated each day. Daily, the floor and walls should be mopped with clean water and soap. Cats and dogs must be kept out of the sick-room. After termination of the illness, the room is to be fumigated with sulphur (for every one thousand cubic feet, three pounds of sulphur is sublimed) and thoroughly aired for a number of days. A strict rule must be enforced that only nurses be allowed to enter the room. After leaving the room and before coming in contact with other persons, nurses should wash the face and hands perfectly with soap and water. Older children should not expectorate into handkerchiefs, but into suitable cuspidors containing disinfecting fluid. The attending physician must have strict supervision over the cleansing and disinfection. He should always take care for hygiene in the household, and in those families which have not sufficient seclusion for the healthy children he should, if possible, provide quarantine for the sick. Another very important point is the compulsion by law of notification of such diseases. Parent, physician, teacher, and the police ought, under penalty, be bound to report such diseases. By such means only can the sanitary inspector take the requisite measures energetically and effectually to suppress a threatened epidemic. Bed clothing, mattresses, woollen goods, garments, etc., should be cleaned in public disinfecting institutions. Kindergartens, schools, etc., should constantly be superintended by a physician. Children who are suspected of being in the prodromal stage of diphtheria, scarlatina, measles, or whooping-cough should be strictly kept away from these places. Likewise should be excluded healthy children whose brothers or sisters may be infected with any of these maladies. If we accomplish these points, which belong to rational prophylaxis, good results certainly cannot fail.—*Pediatrics.*

Gonorrhœa in Women from a Medico-Legal Standpoint.—Dr. Neisser discusses this important question with especial reference to the importance of the diagnosis, which, he affirms, cannot be positively made without the aid of the microscope. A secretion may be present which bears an exact resemblance, macroscopically, to gonorrhœal pus, but contains no cocci, or, in fact, any bacteria whatever (*American Journal of the Medical Sciences*). Moreover, it is impossible to determine the time at which infection occurred, since its course differs so widely in different subjects. When the cervical canal is affected, but not the urethra, symptoms may be absent. The writer denies the truth of the statement that obscure acute gonorrhœal infection in the female may cause a chronic discharge in the male; the gonococci always possess the same virulence, and when they come in contact with healthy mucous membrane produce an acute inflammation. This explains the violent gonorrhœal attacks in newly married women whose husbands regard themselves as entirely cured, and also the similar acute infection of men after intercourse with women whose physicians had discharged them as free from disease. In both instances the secretion is found to contain a few scattered cocci, which are found only after a long search. In the chronic cases the characteristic appearance of the gonococci within cells is often wanting, and the culture test is frequently unsatisfactory. In short, the microscopical diagnosis is often exceedingly difficult. Still, this is the only one which should be admitted as positive in a court of law. Dr. Simon has recorded the following interesting case. A man, aged thirty-seven years, was accused of having committed rape upon a little girl, five years of age, and of having infected her with gonorrhœa. An examination of the greenish pus which escaped from her vagina showed that it contained Neisser's cocci. The accused denied that he had had urethritis or any venereal trouble since an attack of clap fifteen years before, which had been promptly cured. Careful and repeated examinations of his urethra showed an entire absence of any abnormal secretion. A bacteriological examination of the urinary sediment demonstrated the presence of numerous epithelial cells containing bodies which somewhat resembled gonococci, but which, when subjected to staining by Gram's method, failed to respond to the ordinary test. Under these circumstances it was im-

possible for the expert to submit a positive opinion. Hence the inference that, when the question of the specific nature of an old urethral discharge is to be decided, too much reliance should not be placed on the bacteriological evidence. Even when cocci are demonstrated in the vaginal secretion, the origin of the infection, whether direct or accidental, may remain in doubt.

Types of Respiratory Movements.—As the outcome of a study of types of respiratory movements prosecuted in the hygiene laboratory of the Lawrence Scientific School at Boston, Fitz (*Journal of Experimental Medicine*, November, 1896, p. 677) concludes that children of the two sexes differ very little in the types of their respiratory movements; that between girls and women and boys and men there is little or no difference in respiratory type; that child-bearing does not permanently affect respiration; that the natural type of respiration for both sexes is one in which the movement is balanced equally or nearly so between chest and abdomen, the abdominal movement being somewhat in excess; that in typical unconstricted individuals the chest contributes about the same bulk of air as does the abdomen; that constricting dress causes preponderance of thoracic movement in ratio to its restriction of abdominal movement and to the sensitiveness of the nervous co-ordination.

Is Rheumatoid Arthritis a Microbial Disease?—According to the *Hospital*, the pathology of this disease has been brought to the front by the researches of Wohlmann and Bannatyne, which render probable a microbial origin for this disease. They found in twenty-four cases out of twenty-five one and the same organism, often in great numbers, which probably enters the system through some catarrh of the digestive or genito-urinary organs, notably through the tonsils, and affects several joints. Here it multiplies in the synovial membrane, ligaments, cartilages, and bone marrow, giving rise to erosion. It secretes a poison which acts on the nervous system, producing muscular atrophy, pigmentation, and tachycardia. They obtained the organism by aspirating with aseptic precautions the affected joints. Blaxall, who worked with them, recommends that a thin film of the fluid should be dried and fixed by passing several times through the flame. The glass is then dipped in dilute acetic acid, well washed and again dried, placed on a saucer of aniline methylene blue, and left in a dark moist chamber for from three to five days. It is then washed for some hours, rinsed in distilled water, dried, and mounted. Carbol fuchsin, diluted with one-third of distilled water, will give fair results in twenty-four hours, and requires a final washing in thirty per cent. of alcohol. The organism appears to be a bacillus which stains only at the two ends, and resembles at first sight a diplococcus. No chains or masses are to be seen, and under Gram's method it is decolorized. Rapid staining can be effected by mixing the synovial fluid with methylene-blue stain, drying and fixing, and then simply washing with water. Cultivations in beef broth show after the third day gold-dust-like particles, and on agar tubes a fine film is formed by the growth. The organism has also been obtained from the blood, and does not appear to be present in joints affected with other diseases. Injections into rabbits seemed to produce some affection of the joints, but further observations are needed on this point. The disease, according to these authors, occurs chiefly in women, most often in early adult life and at the climacteric, often following acute rheumatism and uterine disorders. It usually causes painful spindle-shaped swellings of the proximal interphalangeal joints of the ring and middle fingers on both hands together. Then follow in regular order affections of the wrists, the rest of the fingers, the cervical vertebræ, and the jaw, knees, elbows, ankles, and shoulder. There is at first no grating, but secondary osteo-arthritis may follow with erosion of cartilage, eburnation, and overgrowth of bone. The temperature is raised a degree or more in the evening. Besides the anæmia, muscular atrophy, and pigmentation, we may find fingers which "go dead," and even gangrene and ecchymoses occur. Tonic treatment with hot baths and guaiacol to the affected joints seem to give the best results.

A New Method of Localizing Brain Lesions.—At a late meeting of the Royal Academy of Medicine in Ireland, a report of which is published in the *Medical Press*, Mr. Robert Cox read a paper on "A New Method for Localizing Brain Lesions," and exhibited the necessary apparatus for its employment. He poined out that there was need of a more perfect method of locating the important areas of the cerebral cortex on the overlying surface of the scalp, seeing that most, if not all, the methods generally employed are either limited in their scope or complicated in their application, while many give rise to error by the use of a standard measure, the inch or the centimetre, for varying surfaces. He thought the method which he was about to describe would be found devoid of these objections. For its use two things were necessary—(*a*) an instrument which he had invented and called a cerebrographometer, and (*b*) a diagrammatic map of a hemisphere of the brain, prepared from readings made by the use of the same instrument on the cadaver and casts of the brain *in situ*. This map might be substituted, or augmented, by a list of indices made in the same way. The instrument consists entirely of the mechanical device technically known as "lazy tongs" formed into a circle, with two accessory loops attached to the circle by their ends in such a way that they arch over it at right angles to each other. One loop bears the numerals, beginning at each end with 1, and ending in the middle with 10; while the other loop has the letters from A to V in consecutive order from before backward, that bearing T forming the junction with the circle behind. The map is made on a gnomonic projection, with the radii or longitudinal lines marked by letters, and the semicircles or lines of latitude by numerals. In using the instrument it is necessary to extend it in all parts, and apply it to the head with the rivet forming the junction of the lettered loop with the circle in front on the glabella, and the rivet marked V at the other end to the occipital protuberance; then to press down the loop between these two points in the middle line, and close the circle round the head on such a plane that the numeral 10 will rest on the lettered band. The instrument is then in position, when, to find any given point—say Broca's lobe—it is only necessary to consult the map or list of indices for the bearings there given, as "C 4, left side," and place the 10 of the numbered loop on the C of the lettered loop, when the numeral 4 will lie over the part. Having thus shown the simplicity of the method, for the carrying out of which no recourse need be had to any science, and the almost automatic action of the cerebrographometer, he proceeded to explain its accuracy, showing that it was applicable to all-sized heads, and formed its own unit of measurement for each, thus eliminating the errors due to the use of a standard measure for a varying surface. The two fixed points taken, the glabella and the occipital protuberance, place the circle on that plane considered so important by Professor Fraser as bearing a fixed relation to all important parts of the brain. His opportunities of testing its accuracy were very few, but in those it gave excellent results, while, with regard to Rolando's fissure, perfection seemed to have been reached.

CYSTITIS DUE TO THE BACILLUS COLI COMMUNIS.

CYSTITIS in children may be due to stone, new growths, tuberculosis, or to any cause that induces retention of urine. It may also be one expression of a general infectious process. The form that is characterized by alkaline and ammoniacal urine is sufficiently rare. French writers call attention to cases in which the urine gives normal reaction, though it contains rod-like micro-organisms mixed with the pus cells. To these Clado gives the name of septic vesical bacteria. Albarran calls them pyogenic bacteria. More extended investigation shows that the organism is the well-known bacillus coli communis, always present in the intestinal tract, and which may, under favoring conditions, enter the body and produce disease. Barlow, Schmidt, and others have shown that the entrance of the bacillus coli communis into the bladder produces a definite and characteristic cystitis.

This coli-bacillic cystitis is not infrequent in children, especially among girls. In 1894 Escherich reported seven cases in little girls, the ages of five ranging from seven to nine years, while the other two were respectively six and thirteen months old. The same symptoms existed in all—general condition good; frequent urination, with burning sensation during micturition; and the bacillus coli communis found in great numbers in the urine. Washing out the bladder with a weak solution of creolin and salol internally served to effect a complete cure.

Yet further clinical reports, according to Frumpp in a recent German journal,[1] show that coli-cystitis is not so light an affair as Escherich's observations would seem to indicate. Grave complications may arise and death supervene. Frumpp gives the results of twenty-nine cases under personal observation. Of these, eight were of boys, and twenty-one of girls. Twelve patients were two years old, the youngest was aged five weeks, and the oldest nine years. The disease appeared under two forms, mild and severe. In the first there were local symptoms only, the body was well nourished, and the course and termination of the disease were favorable in every way. Ten cases were of this nature. In three, vulvo-vaginitis also existed. In the severe form there is marked change in general nutrition, rapid emaciation, and at times strangury so pronounced that fifteen minutes are required for micturition, the urine being voided drop by drop and with great effort. Pain may be spontaneous or induced by pressure in the region of the bladder and occasionally in the kidneys. Hæmaturia, when it exists, is usually transient. During the entire course of coli-cystitis, there is always danger of an ascending inflammatory process, causing ureteritis, pyelitis, and nephritis, with a resulting uræmic poisoning. Then apathy appears, together with marked and increasing emaciation, somnolence, vomiting, and collapse. Two cases of Frumpp's resulted in an ascending inflammation that caused nephritis and death.

Urinalysis in the two forms of coli-cystitis differs in degree rather than kind. In benign cases the urine is cloudy, acid in reaction, and contains a minute quantity of albumin. Its color is usually normal, though it may be pinkish or opalescent. The odor is stale or slightly fetid. The microscope reveals isolated epithelial cells from the bladder, polynuclear leucocytes, together with masses of rod-shaped micro-organisms, usually separated from the cellular elements. In the severe or grave form of the disease there are considerable albumin and a disagreeable and fetid odor of the urine: leucocytes are abundant, sufficient in number to form a deposit equal to about one-third of the matter voided. This urine is rich in peptones, acid in reaction, contains numerous pus cells, epithelial cells, and casts.

Mild cases recover in from one to two weeks, some without treatment of any kind whatever. Severe cases vary in duration. The best results are obtained by washing out the bladder with a warm solution of lysol, and by giving salol in appropriate doses.

How does the bacillus coli communis get into the bladder? And does it always cause cystitis when there? Interesting observations on urine in disease reveal its presence where no cystitis exists. Escherich explains the greater frequency of coli-cystitis in girls upon purely anatomical grounds, assuming that infection may come from without and by means of direct contact of excrementitious products with the mucous surfaces of the vagina and urethra. Others think there may be a direct migration of the bacilli through the walls of the intestine into the bladder. Denys thinks this possible only when there is a lesion and hyperæmia of the intestine. Czerny, Escherich, and Frumpp have found the bacillus coli communis in the blood in cases of enteritis. Work on the cadaver has also demonstrated its presence in various organs of the body. A general coli-bacillus poisoning is always possible, for the virulence of this particular micro-organism, under favoring conditions, has not been exaggerated.

[1] Deutsch. med. Wochen., September 10, 1896.

THE HIPPOCRATIC OATH.

WE have been asked by a correspondent regarding the Hippocratic oath, taken by physicians upon graduation.

He states that he has inquired as to the substance of this oath of many physicians who have been unable to give him a satisfactory answer. He is under the

impression that this oath requires a physician to respond to any call made upon him for professional services, regardless as to whether those services will receive compensation or not. He holds that such a demand would be unjust under present conditions, especially in cities and large towns, where hospitals and city physicians are provided for the poorer classes; while in smaller towns the law provides that the poor shall receive medical attention at the expense of the public. He is satisfied that a large number of men take this oath as a matter of form, without any conception of what they have to observe. For the benefit of our correspondent, and those whom he has questioned, we give the following translation of the oath in full:

"I swear by Apollo the physician, and Æsculapius, and Health, and All-heal, and all the gods and goddesses, that, according to my ability and judgment, I will keep this oath and this stipulation—to reckon him who taught me this Art equally dear to me as my parents, to share my substance with him, and relieve his necessities if required; to look upon his offspring on the same footing as my own brothers, to teach them this art, if they should wish to learn it, without fee or stipulation; and by precept, lecture, and every mode of instruction, I will impart the knowledge of the Art to my sons, and those of my teachers, and to disciples bound by stipulation and oath according to the law of medicine, but to none others. I will follow that system of regimen, according to my ability and judgment, I consider for the benefit of my patients, and abstain from whatever is deleterious and mischievous. I will give no deadly medicine to any one if asked, nor suggest any such council; and in like manner I will not give to a woman a pessary to produce abortion. With purity and with holiness I will pass my life and practise my Art. I will not cut persons laboring under the stone, but will leave this to be done by men who are practitioners of this work. Into whatever houses I enter, I will go into them for the benefit of the sick, and will abstain from every voluntary act of mischief and corruption, and, further, from the seduction of females or males, of freeman and slaves. Whatever in connection with my professional practice or not in connection with I see or hear, in the life of men, which ought not to be spoken of abroad, I will not divulge, as reckoning that all such should be kept secret. While I continue to keep this Oath unviolated, may it be granted to me to enjoy life and the practice of the art, respected by all men, in all times. But, should I trespass and violate this Oath, may the reverse be my lot."

A reference to prevailing codes of ethics will show that no such requirements as our correspondent suggests are made. He is privileged to use his own judgment in accepting or rejecting any case, but, having accepted, he is expected to do his work conscientiously without regard to compensation.

It may be observed that the points raised are not touched upon in the "oath." The Hippocratic oath shows the high standard of honor, integrity, the spirit of brotherly love and philanthropy which it has been the aim of the profession to maintain since the beginning of the science of medicine. In taking this oath to-day we understand that the physician binds himself to preserve the dignity, purity, and honesty of the profession, that he shall ever be guided by sound judgment and high moral principles.

TUBERCULOSIS AND TYPHOID.

While much attention is being given to the dissemination of tuberculosis through milk supplies, and much is being done by the authorities to lessen the dangers from this source, comparatively little is said about the dangers of milk as a carrier of the germs of typhoid, scarlatina, and other diseases.

Some recent reports would seem to indicate that there is much on this side of the milk question which will repay investigation.

HEALTH BOARDS

Should be most careful in the way they place upon physicians what may be looked upon as needless burdens. In order that all good regulations should continue to receive the support and co-operation of the profession, no bad ones should be interpolated which might tend to bring discredit upon the whole by reason of their impracticability and burdensomeness.

News of the Week.

The American Medical Editors' Association.—The meeting of this association will be held in Philadelphia, under the presidency of Dr. H. A. Hare, June 1–4, 1897.

The Possession of Anæsthetics is Illegal.—Governor Black has signed a bill designed to restrict the use of "knock-out drops." The bill makes it a felony for a person other than a duly licensed physician to have an anæsthetic on his person with the intention of administering the same to another person, and makes the finding of the same on the person by any one presumptive evidence of guilt.

An Anticigarette Bill has been introduced into the legislature of this State and has been reported favorably by the committee on public health. The bill forbids the sale of cigarettes to minors, and provides that dealers in cigarettes shall pay a license fee. The bill also prohibits the sale of cigarettes within two hundred and fifty feet of a church or school.

Proposed Change in the Missouri Medical Law.—A bill has been introduced into the Missouri legislature which proposes to take the right to license physicians to practise medicine in that State out of the hands of the State board of health, and to place it in the hands of a board of medical examiners consisting of five members to be appointed by the governor.

The Spitting Nuisance.—It is reported that the city council of Springfield, Mass., has passed an ordinance prohibiting spitting upon the sidewalks. As we noted last week, a beginning has at last been

made in this city in the enforcement of the rule against spitting, the notices of which for so long afforded amusement to street-car conductors and elevated-road guards. The *Medical News* says that a well-known Chicago lawyer, of prominent social and political position, has been arrested for expectorating in a street car. He threatens to sue the company for $50,000 damages. *The Sanitarian* says that among the suggestions made at St. Louis, on account of the difficulty in the enforcement of the order of the health department against spitting on the floors of cars, one is that a few cars be run over the lines with the placard "spitters' cars" on their sides.

Philadelphia Polyclinic.—By the will of the late Sarah Phillips the sum of $10,000 is devised to the Philadelphia Polyclinic and College for Graduates in Medicine.

Philadelphia Pediatric Society.—A stated meeting of the Philadelphia Pediatric Society was held on March 9th, the president, Dr. J. P. Crozier Griffith, in the chair. Dr. D. J. Milton Miller related a case of extensive subconjunctival hemorrhage in a child suffering from whooping-cough, exhibiting a striking picture of the aggravated complication. Dr. Miller also read a paper on "Hyperpyrexia as a Fatal Termination in Entero-Colitis, with Remarks on the Use of Opium in This and Allied Affections." He pointed out the danger of using opiates to restrain the activity of the bowels when diarrhœa was a conservative process on the part of the organism to rid itself of noxious and toxic matters. Under these circumstances there is danger also in the use of milk and other fermentable food; so that good results may be looked for from total abstinence from food or from the use of albumin water, beef juice, and the like, for varying periods of time, and the employment of rectal irrigation. Dr. S. M. Hamill read a paper on "Glandular Fever," reporting cases and reviewing the literature. The discussion developed the fact that there is a marked and legitimate difference of opinion as to whether so-called glandular fever is a distinct entity or only a secondary manifestation of some primary and obscure infective process. Dr. J. H. Jopson reported a case of malignant endocarditis in a new-born child. Dr. A. E. Taylor reported a case of pulmonary thrombosis in a child the subject of congenital syphilis. Dr. Jos. Sailer also briefly reported a case of endocarditis in a young infant.

Aid for the Cuban Wounded.—A number of physicians, dentists, and pharmacists of Buffalo recently formed an association having for its object to provide the army of liberation in Cuba with the necessary remedies and surgical appliances for the wounded.

A New Rule Concerning Contagious Diseases.—The health board has adopted a new rule regarding contagious diseases among school children. The old rule has been to exclude from school all children living on a floor where there is a case of diphtheria, measles, or other contagious disease, but this has been found to be unnecessarily stringent. It has now been decided to insist even more strongly than before upon isolation of the sick, but to forbid attendance at school of only the other children of the same family, the children of other families living on the floor being permitted to go to school as usual. It is proposed also to have the board's inspectors visit daily children ill with contagious disease.

Dr. George E. Doty was the author of the article on "Diphtheria and Scarlet Fever," in the issue of February 20th, and not Dr. G. E. Daly, as printed.

Congress of American Physicians and Surgeons.—The fourth session of this congress will be held in Washington, May 4, 5, and 6, 1897, under the presidency of Dr. William H. Welch, of Baltimore. The following are the subjects for discussion at the general meetings: "The Gouty and Rheumatic Diatheses, and their Relations to Diseases of the Eye;" "Otology in its Relations to General Medicine;" "Internal Secretions considered in their Physiological, Pathological, and Clinical Aspects;" "Deformities of the Hip-Joint, especially Congenital Dislocations;" "The Classification of Acute General Peritonitis: the Prognosis and Treatment of the Different Varieties." The address of the president of the congress will be delivered on the evening of Wednesday, May 5th. The meetings will be held in the Columbia Theatre, corner of Twelfth and F Streets, N. W.

Dr. Nicholas Senn has been invited to deliver one of the general addresses before the Twelfth International Medical Congress at Moscow.

The Plague.—A telegram from Bombay, dated March 11th, states that the total number of cases of bubonic plague in that city, up to date, is 9,032, and 7,546 deaths have resulted. In the whole presidency, to date, there have been 14,856 cases of the plague reported, and 12,204 deaths have been recorded.

Cholera in India.—A serious outbreak of cholera at Rewa, in India, is reported. It is stated that one hundred and sixty deaths occurred in two days, and that energetic steps are being taken to check the progress of the disease.

Blindness in Northern Europe.—The ratio of blind persons to 100,000 inhabitants is in Denmark 53, Sweden 88, Norway 128, Finland 155, Russia 200. There is less blindness in cities than in the country, the proportion being in Norway 83 to 145.

Jefferson Medical College.—The Philadelphia chapter of the Alumni Association of Jefferson Medical College held a scientific meeting in the college building on March 9th, Dr. H. A. Wilson occupying the chair. Dr. A. H. Hulshizer, the president of the chapter, read a paper on headaches and their treatment. After the meeting a reception was held by Dr. D. Braden Kyle.

Wetnurses for Invalids.—A writer in *The Lancet* says that during an attack of dysentery he was advised to take milk and soda water, but found that milk warm from the cow was more beneficial. He asks if there is not some sucker arrangement to attach to a cow's udder by which milk can be drawn off and

sucked through a tube without being exposed to the air at all? If delicate growing children and invalids would take milk in this way, he thinks it would do them far more good than milk, especially boiled milk, which has been exposed to the air. He inquires whether wetnurses ever give their services to invalids, and wants to know, if not, why not.

The Jersey City Water Supply.—The company which has been supplying Jersey City with water has notified the authorities that it will have to limit its supply by reason of the prior claims of other cities using water from the same source. In that case Jersey City will have to go back to the Passaic River for a part of its supply, a river which a recent legislative committee has shown to be polluted far beyond the limit of safety for the users of its water.

The Atlantic County (N. J.) Medical Society.—The annual meeting of this society was held in Atlantic City on March 4th. Dr. W. E. Darnell read a paper on "The Clinical Significance of the Discharge in Infantile Diarrhœas." The election of officers resulted as follows: *President*, Dr. W. Blair Stewart; *Vice-President*, Dr. A. D. Cuskaden; *Secretary and Treasurer*, Dr. Walter Reynolds; *Reporter*, Dr. W. E. Darnell.

An Insanitary Court House.—The board of health of Newark, N. J., has been investigating complaints concerning the sanitary condition of the county court house. It has found the complaints well founded and has called the attention of the board of freeholders to the lack of good sanitary arrangements, and ordered that the place be put in sanitary condition within ten days or the alterations would be made at the expense of the county.

A New Symptom of Morphine Poisoning.—A prisoner in the Raymond Street jail, in Brooklyn, recently attempted suicide by morphine. In its account of the affair, the *Evening Post* said that the man was found in his cell by a keeper, in a half-conscious condition. The keeper tried to arouse him, and when he failed the matter was reported to the warden. The latter "immediately detected the odor of morphine," and so the diagnosis was made.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending March 13, 1897: March 9th.—Surgeon T. C. Craig detached from the marine rendezvous, New York, and ordered before retiring board, March 16th, then home and await orders; Assistant Surgeon R. G. Broderick detached from the *Constellation*, March 15th, and ordered to the New York navy yard, March 17th. March 10th.—James C. Pryor commissioned as assistant surgeon from February 27th. March 12th.—Surgeon H. E. Ames detached from the *Detroit* and ordered to the *Cincinnati;* Surgeon D. N. Bertolette detached from the *Minneapolis*, ordered home, and granted three months' leave; Surgeon N. H. Drake detached from the *Cincinnati* and ordered to the *Minneapolis;* Assistant Surgeon G. C. Hubbard detached from the *Cincinnati* and ordered to the *San Francisco.*

The Cocaine Habit.—It is proposed to prohibit the sale in Chicago of catarrh snuffs and balms and other quack remedies which contain cocaine. An ordinance to that effect has been introduced by one of the aldermen. It is said that over forty victims of the drug have been brought into the police courts in the past month.

The Russian Women's Medical Institute.—The Tsar has given a sum equivalent to $30,000 for the erection of dormitories for the students of the St. Petersburg Medical Institute for Women of the orthodox faith.

Dermatology and Syphilology at the Twelfth Annual International Medical Congress.—The following is the list of subjects selected by the committee on organization of the eighth section of the International Medical Congress, which meets in Moscow, August 7 to 14, 1897: Dermatology: Actinomycosis, primary tuberculosis of the skin, cutaneous sarcomatosis, acanthosis nigricans, pathogeny of alopecia areata, blennorrhagic eruptions, eruptions of malarial origin, hydrargyric eruptions, treatment of scleroderma, treatment of rhinoscleroma. Syphilology: When should we begin the treatment of syphilis with mercury? How long should the treatment of syphilis be continued? Is it necessary to treat syphilis from the moment of the appearance of syphilitic accidents, or to institute a provisional treatment without these accidents? The modification of the anatomical elements of the blood in syphilitics during the condylomatous period; The methods of treatment of syphilis by soluble and insoluble mercurial injections. It is hoped that there will be a creditable representation of American dermatologists and syphilographers at this meeting, and it is requested that all proposing to contribute to the scientific discussion shall send the titles of their papers to Dr. Prince A. Morrow, New York, the president of the section for the United States.

Obituary Notes.—Dr. Joseph F. Gallagher, of Freeland, Pa., died on March 3d, of pulmonary tuberculosis. He was born in Yorktown in 1872, and was graduated from the Jefferson Medical College in 1894. After graduation he became an assistant to Dr. Neale, of Upper Lehigh, remaining with him about a year, when he resigned to accept the position of assistant superintendent of Ashland Hospital. Sickness compelled him to resign this place a year ago. In his brief medical life he had shown great skill and coolness as an operator.—Dr. Sumner A. Mason died suddenly at his home in this city on March 12th. He was a graduate of the University of Pennsylvania in 1868.—Dr. E. P. Strunk, of Brewster's, N. Y., was killed by a train on the New England Railroad on March 12th. He was born in Poestenkill, N. Y., and was forty-seven years of age. He had practised medicine in Brewster's since his graduation, twenty-three years ago.—Dr. William C. Roller died suddenly at Hollidaysburg, Pa., on March 11th, at the age of fifty-nine years. He was for many years president of the Blair County Medical Society and at the time of his death president of the Hollidaysburg school board.

Ridiculous Old Fogyism.—The *Medical Press* gives an almost incredible instance of British conservatism run mad. "The sublime and the ridiculous," it says, "seem to be curiously illustrated in the regulations, written and unwritten, which belong to the Royal College of Physicians, London. But perhaps the most remarkable of all is that which relates to syphilis. It appears to be the case that no fellow or member of the college is permitted to publish anything on this subject. We understand that only recently a fellow of the college was severely taken to task by the president, for having so far offended against the traditions of the college as to publish an important communication upon the forbidden subject. The grounds of the objection were stated to be that syphilis was a surgical and not a medical disorder. We can scarcely refrain from saying, 'What a grandmotherly institution the College of Physicians, London, is.' It is really difficult to credit that the facts as above stated could be true at this period of the world's history, with the dawn of the twentieth century at hand. . . . Is the progress of medical science to be fettered and controlled by such narrow and illiberal-mindedness, based upon fatuous sentiment, as that which appears to pervade the noble—we had almost said ignoble—institution in Pall Mall east? Why should a fellow of the College of Physicians who has worked laboriously and well on the subject of syphilis be debarred by his college from publishing his it may be valuable records and so add to the quota of medical knowledge? Probably few in the profession will be able to understand that such things as we have here mentioned could be the case, but inquiry would soon satisfy them that we have not exaggerated the facts."

Philadelphia County Medical Society.—A stated meeting of the Philadelphia County Medical Society was held on March 10th, one of the vice-presidents, Dr. Edward Jackson, in the chair. Dr. H. A. Hare read a paper on "Anæmia and Leukæmia," exhibiting a case of splenic leukæmia, one of pernicious anæmia apparently cured, and one of anomalous type with enlarged spleen, pronounced anæmia, and an increased proportion of lymphocytes, though without actual increase in the number of colorless corpuscles. He reported besides three other cases of pernicious anæmia. He indorsed the principle that when the hæmoglobin is disproportionately diminished, iron is the remedy indicated, while, on the other hand, when the number of erythrocytes is reduced, the better remedy is arsenic or mercuric chloride. Dr. Joseph Price made "A Report of a Mixed Group of Abdominal Sections, with Discussion of Methods." Dr. George Erety Shoemaker read a paper entitled "Recent Gynæcological Surgery at the Methodist Hospital—Forty-one Consecutive Abdominal Operations, with one Death, including Twelve Hysterectomies."

A Dispensary Patient.—The dispensary abuse has reached the stage of newspaper investigation. The *Mail and Express* has been conducting a quiet investigation of the worthiness of the applicants for dispensary relief, and says that discoveries of unique, almost grostesque, interest have been unearthed. The president of one of the largest municipal railroad corporations has been identified as a regular attendant at one of the dispensaries. A free patient at an uptown hospital is the owner of three houses on Third Avenue. Other patients have turned out to be people of excellent financial standing in towns and cities remote from New York.

Medico-Chirurgical College.—The board of trustees of the Medico-Chirurgical College of Philadelphia has elected the following faculty for its new dental department: D. D. Smith, D.D.S., M.D., dean of the faculty and professor of operative dentistry and dental pathology; Robert M. Mones, D.D.S., professor of dental prosthesis and dental metallurgy; R. Walter Starr, D.D.S., professor of orthodontia, dental materia medica, anæsthesia, and bridge work; John V. Shoemaker, M.D., LL.D., professor of materia medica and therapeutics; Ernest Laplace, M.D., LL.D., professor of surgery and special oral surgery; Isaac Ott, M.D., professor of physiology; G. H. Meeker, B.S., professor of chemistry. A professor of anatomy is yet to be selected.

An Enterprising Business Man.—In some interesting remarks upon the hospital business, and to illustrate the commercial tendency of medical practice, the editor of the *Cincinnati Lancet-Clinic* says there is a physician in that city who has a card with the names of eight different hospitals, with rates per week in each, the reader being cautioned, however, that this charge does not include professional services. It is added that the patients have the privilege of selecting their own hospital. The whole affair gives an impression that he is on the special staff of all of those institutions, but any reputable physician has precisely the same privilege in every one of the institutions named. This is a little bit of enterprising advertising, our contemporary says, that is a trifle new thereabouts, but we doubt not it will soon cease to be novel.

The Pathogenesis of Addison's Disease.—As the result of an experimental investigation, Boinet (*Revue de Médecine*, 1897, No. 2, p. 136) concludes that the theories that attribute the manifestations of Addison's disease on the one hand to failure in function of the suprarenal glands and on the other hand to disease of the abdominal sympathetic system of nerves represent each the truth in part, either alone being inadequate to explain the symptoms. In case of absence or of integrity of the capsules, the nervous theory must necessarily be invoked. Both clinical and experimental evidence, however, shows that pathologic or experimental destruction of the capsules acts not only through ascending and secondary degeneration of the sympathetic nerves and their ganglia, but also through the loss of function of the capsules. This suppression of function favors the retention in the blood, in the viscera, and in the muscles of toxic products that appear to play a certain rôle, either in the formation of pigment in the blood, or in the production and augmentation of asthenia.

A Medical Consul.—Dr. David Cerna has been appointed Mexican consul at Galveston, Texas.

Clinical Department.

STRANGULATED OVARIAN CYST COMPLICATING PREGNANCY.

By J. D. JONES, M.D.,

UTICA, N. Y.

Mrs. H., twenty-nine years of age, married. She menstruated last, June 17, 1896. She had always been well, and was not aware that there was anything the matter with her except that she was in the family way. She was a weaver by occupation and went to the mill to work as usual Monday morning, September 28th. Soon after beginning work, she was taken with cramps and was obliged to go home. The colicky pains continued severe all day, and I saw her first between five and six o'clock that same evening. She was then in great pain. Her pulse and temperature were normal. There was no vomiting. The bowels had moved daily, including the one on which she was taken ill. There was no tympanites or abdominal tenderness. She was given a full dose of morphine hypodermically.

The next morning the pain was much less and the bowels had moved again in response to an enema. On making a more careful examination of the abdomen at this visit, the pregnant uterus was felt rising out of the pelvis and a rather flat globular swelling could be felt in the left hypochondrium, tender on pressure and dull on percussion. The rest of the abdomen was not tender or distended. Tuesday night she began to vomit, or gulp rather, and her pulse and temperature rose a little. The tenderness was more diffuse and there was considerable tympanites.

Wednesday morning the symptoms of general peritonitis were well marked. At eleven o'clock Wednesday morning she was admitted to St Elizabeth's Hospital. Her temperature then was 99.2 F. and her pulse 130. No positive diagnosis was ventured. At two o'clock the same day, the abdomen was opened in the left hypochondrium, over the most prominent part of the swelling. There we found what no one who had seen the case suspected, an ovarian cyst black from strangulation, caused by rotation of its pedicle. A portion of the fluid was withdrawn with an aspirating needle, and the sac rotated so as to untwist the strangulated pedicle and ligated through very questionable tissue close to the left horn of the uterus. The stump was carefully surrounded with iodoform gauze, which was brought out through the lower angle of the abdominal wound. This method of dealing with the stump was thought to give a better chance of escaping infection of the interior of the uterus and disturbance of the pregnancy than would taking out a wedge-shaped piece from the left horn and suturing it. Five or six days after the operation an abscess formed in connection with the stump, and discharged through the drainage opening at the lower angle of the abdominal wound. Subsequently, as the uterus rose in the course of the pregnancy, it discharged through the upper end of the abdominal incision.

October 23d, or twenty-four days after the operation, she had a severe chill and her temperature rose to 104° F. It remained high till the morning of the 25th, when she miscarried. The fœtus was alive; it measured twelve inches in length and weighed seventeen and one-half ounces.

As the uterus receded into the pelvis, the abscess in the vicinity of the stump "resumed business in the old stand" at the lower angle of the abdominal wound. In a few days it closed permanently, however. She left the hospital November 11th, forty-two days after the operation, and immediately resumed her work as weaver. She is now in good flesh and feels perfectly well. I have not examined the wound since she left the hospital, but suspect from her statements that a hernia is forming at the seat of drainage at the lower angle of the wound.

This case is particularly interesting as showing the difficulty in making an exact diagnosis in abdominal lesions. Although the cyst was as large as the adult head, this woman was not aware of its presence. Its forced residence in the left hypochondrium added greatly to the obscurity of the diagnosis. The case also impressed on my mind the advisability of opening the abdomen in all cases of general peritonitis of obscure origin.

24 Genesee Street.

TWO PRACTICAL WRINKLES IN THROUGH-AND-THROUGH DRAINAGE.

By Drs. PAUL TUPPER and V. P. BLAIR,

ST. LOUIS, MO.

The following is applicable in any part where a through-and-through drainage tube is used.

The procedures were suggested and are particularly effective in overcoming certain difficulties in the maintenance of drainage in an empyema.

The first has reference to keeping the tube patulous by removing collections of pus and cutting off the granulations which grow down into the fenestræ of the tube. It consists of an ordinary drainage tube with the requisite number of fenestræ, through the full length of which (previous to insertion) a strong silk ligature has been passed. This silk is of a length of about four times that of the tube, and has fastened at about a tube's length from one end of it either a split shot, the size of the calibre of the tube, or a section of rubber tubing. If a section of tubing is used, and this is more satisfactory, it should be of pure gum and just large enough to pass through the tube with some friction. The tube is inserted in the wound in the

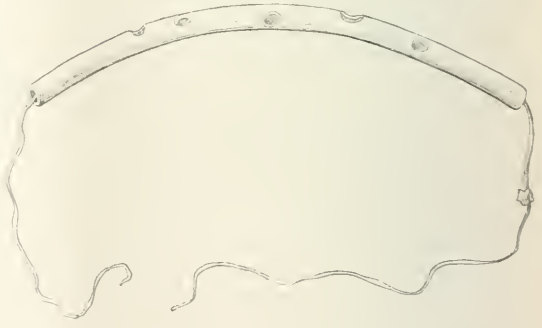

Fig. 1.

usual way and both ends are held with safety pins inserted in such a manner as not to infringe on the lumen. The two ends of the silk are knotted to form an endless string with the knot on the outside. When the tube becomes occluded, it is first moved in the sinus to cut off the granulations, and then the drag is pulled through the tube and everything in the form of pus is completely removed.

The second refers to the secondary or horsehair drainage. This consists of a strand of horsehair of the required thickness which has, at the proper distance from each other, two silk threads tied tightly

around the strand with one end of each cut short and the other left the length of the drain. The strand is then cut squarely off at each end, one-fourth of an inch beyond the knotted silk. Then the knot and end of strand are covered with sealing-wax which is shaped into a round probe and with the silk cord protruding from the tip. To insert the horsehair, the silk is attached to the silk of the drag and the probe end is

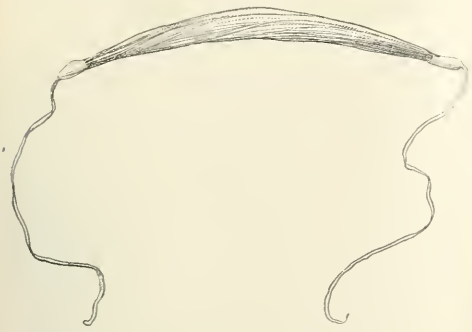

Fig. 2.

brought up snugly into the end of the tube. Then, as the tube is removed, the drain follows without giving extra pain. In case there is no cord in the tube, the silk of the drain can be threaded through a curved needle and the needle passed through the wall of the tube from within out. Then the end of the drain can be drawn up into the tube as before. After the drain is in place the two silk cords can be knotted. This will be found especially advantageous with children and nervous people; one quick jerk will remove the tube and locate the drain.

319 North Grand Avenue.

EXTREME DILATATION OF THE BLADDER COMPLICATING A RETROVERTED PREGNANT UTERUS.

By J. D. JONES, M.D.,

utica, n. y.

Lucy G., Italian, twenty-eight years of age, married, and the mother of two children. She had a miscarriage April 8, 1896. She menstruated in May. In June she did not come around. About the middle of July her abdomen began to enlarge rapidly. In August she was admitted to one of the hospitals in this city for the purpose of having a laparotomy performed, but before the day of operation she became disgruntled and left.

I saw her first the last week in August. She then presented a central, symmetrical enlargement of the abdomen of about the size and shape of an eight months' pregnancy. No fœtal heart could be heard and the enlargement appeared to contain fluid. By the vagina things were very dark. The cervix could be felt with extreme difficulty, pressed up tightly behind the symphysis. A firm tumor could be felt in the vagina and also through the rectum.

September 10th, she entered St. Elizabeth's hospital for examination. On depressing the posterior wall of the vagina, and making pressure on the tumor felt there, a stream of water was seen to gush from the urethra. A catheter was passed, and one hundred and sixteen ounces of urine were withdrawn from the bladder. This was, of course, attended with complete subsidence of the tumor. The retroverted pregnant uterus righted itself in three days. At first it took very nearly a gallon of boric-acid solution to distend the bladder. She had a sharp rise of temperature and was septic for a few days, and aphthæ formed in the vagina and over the vulva. The bladder was flushed daily with a saturated solution of boric acid and a self-retaining soft-rubber catheter connected with a basin of antiseptic fluid was worn continually. The bladder wall—contrary to what one would expect—recovered its contractility very rapidly, so that on the tenth day of her residence in the hospital it would hold only thirteen ounces of fluid on forced distention, and she could empty it voluntarily. The urgency of poverty made it necessary for her to return home on the eleventh day, but she has had no trouble since.

I saw her January 9, 1897, when I found her about eight months pregnant. I drew five ounces (three hours' accumulation) of normal urine from her bladder, and she said that she held and made her water as well as she ever did.

The cause of the trouble was probably that the uterus—becoming pregnant so soon after the miscarriage, before involution was complete, as she kept her bed only two or three days after that event—assumed a position of extreme retroversion and dragged the bladder with it, producing a kink in the urethra; or possibly the obstruction may have been produced by the pressure of the cervix against the urethra. As the bladder became more distended, the pressure on the fundus was increased and the vicious cycle aggravated.

I have deemed the case worthy of report on account of the extreme distention of the bladder and, contrary to expectation, the complete recovery of its contractility after such extreme and prolonged distention.

240 Genessee Street.

A CASE OF NOMA.[1]

By ALEXANDER MACKENZIE CAMPBELL, M.D.,

resident physician, children's free hospital, detroit, mich

Inasmuch as noma is a disease that is exceedingly rare in this country, it seemed to me a report of the following case might be not altogether uninteresting. So far is it from being a common disease, indeed, that some of our most experienced and distinguished clinicians have never observed it in America and only a few times has it been seen abroad. Upon reviewing the leading American and English medical journals, I find that only about a dozen cases have been reported therein during the last ten years. Allchin[2] says that during seven years in the East London Hospital for Children there were only five cases out of a total of 6,364 admitted, and during thirteen years at the Hospital for Sick Children there were only six cases out of a total of 13,000 admitted. According to Vogel, the older writers in medicine do not seem to have become acquainted with it. The first work upon the subject was by Battus, a Dutch physician at the commencement of the seventeenth century.

On July 18th, 1896, Josephine B——, aged nine years, was brought to the Children's Free Hospital in an emaciated adynamic condition, and in complete exhaustion. Upon examination it was found that she was suffering from valvular disease of the heart, a presystolic murmur being audible. Palpation and percussion revealed considerable dilatation. These conjectures were verified by post-mortem examination. The quantity of urine voided per day was diminished to a few ounces; its examination was negative. The lower extremities and eyelids were œdematous, and there was

[1] Read before the Detroit Medical and Library Association, November 23, 1896.

[2] Keating's "Cyclopædia of the Diseases of Children;" Pediatrics, October, 1896.

marked ascites. Nature had seemingly petered out in her attempt to compensate an irreparable insufficiency.

The following history was elicited. Josephine was born at full term, and was breast fed until the age of twelve months. She was never a rugged child, nor one who indulged in the romps and games common to that period of life when the average child knows no restraint. She had never been attacked by any of the exanthematous diseases excepting measles, which she contracted at the age of three years. During the last year she developed symptoms which indicated that the compensatory action of a diseased heart was on the decline. Seven weeks before coming to the hospital, she fractured her left ulna by falling a distance of ten feet. Her parents fixed that date as the one on which she received her death blow, and stated that she had never been the same after that injury and that she shortly afterward developed the condition described above. This child was one of eight, the rest of the family and the parents enjoying good health. No history of rheumatism, syphilis, or tuberculosis could be traced. Two of the grandparents lived to be over seventy, and the other two died at the age of fifty from "heart disease." Her surroundings had always been such as to retard recovery from any disease or injury. In her home poverty and filth strove for precedence, sunshine and fresh air were strangers. It is more than likely that her heart trouble was congenital.

On admission she was given a hydragogue cathartic, and a half-teaspoonful each of infusion of digitalis and gin every two hours. During her short stay she seemed to improve, but was taken home in a few days through some misunderstanding on the part of her parents. Ten days later she was brought back to the hospital, and her condition was alarming. In addition to the increasing heart trouble, she had developed a case of genuine noma. During her few days at home she complained of a dull pain in the left upper jaw, and asked to have one of her teeth extracted, which the mother did with ease by use of her thumb and forefinger. There had been no previous history of neuralgia. The second time she came under our observation, a part of the left cheek was swollen and of a livid, shiny, waxy appearance. A direct line was palpable which encircled the diseased zone. There was an offensive odor of gangrene. Profuse salivation was produced. An ichorous sanguinolent discharge from the mouth continued throughout the whole course of the disease. On examination, an ulcer was found upon the gum and inner surface of the cheek in close relation to Steno's duct. Treatment was immediately instituted. The child was isolated and the room carefully disinfected. The lesion was cauterized with silver nitrate, the mouth was washed out with a solution of sulphate of potassium, one drachm to the ounce. There was no response. The mouth was cleansed every hour with a saturated solution of boric acid and hydrogen dioxide, but the ulcer spread rapidly. The Paquelin cautery might have proven a valuable adjuvant, but was not used. It was strange, but characteristic of the affection, that the child suffered very little from pain, and during the first few days showed no constitutional symptoms except an intractable diarrhœa, which undoubtedly was caused by her swallowing some of the ichorous discharge from the mouth. Her suffering was by no means proportionate to the gravity of the disease. In a few days three of the teeth of the superior maxillary fell out, and the whole upper left gum became involved. Thus the erosive process continued. The lesion was of a dark ashy hue and its surface was corrugated. It grew deeper and wider, until a large cavity was formed on the inner side of the cheek. On its outside on the sixth morning appeared a bluish-black circular spot. It was about the size of a dime, and indicated that the process had made its way from mucous membrane to integument inclusive. This area continued to enlarge, and on the ninth morning we removed a conical-shaped sphacelated mass, which left a hideous-looking wound and exposed the side of the tongue and upper jaw. Once commenced, the destructive process continued unabated, and within a fortnight the small gangrenous ulcer had enlarged into a mass of broken-down tissue, the removal of which left a ragged circular opening which could not have been covered by a silver dollar. In this case the periosteum and bone of the upper jaw were slightly denuded. The mucous membrane in no other part of the body was affected, as has ocurred in a few instances. Although patients suffering from noma may have a temperature of 104° F., this child's did not exceed 100 F., at any time. The pulse was small, compressible, and rapid, and these characteristics were accentuated as dissolution impended. She died on August 11th, and within three weeks of the first appearance of the disease. Death was preceded by deep coma, and was doubtless caused by exhaustion. Noma usually proves fatal, having a mortality of over seventy-five per cent.

The etiology of this disease is as yet not fully determined. The excessive use of mercury was considered an important factor in the days when it was administered in large and frequent doses. It occurs more frequently in children than in adults, in females than in males. It is said never to have occurred in a nursling. Adults enjoy almost a similar freedom from it, however. Hanson[1] reports a case wherein a man aged fifty-five was attacked by noma and death resulted. The greatest number of cases occur in children between the ages of two and eight. It is said to be more common in damp countries, such as Holland, and "improper hygienic surroundings may determine its occurrence." It has attacked several members under one roof, and has broken out miles away from any place where it ever occurred before. It never becomes epidemic. In May and June, 1891, in the New York Foundling Asylum, an epidemic of measles occurred. One hundred and sixty-five children were affected and noma appeared in seven among that number. The misuse of mercury in treating these cases of measles was considered to have had much to do with causing the complication. In forty-six cases collected by Bouley and Caillault, measles was an antecedent cause in forty-one. Whooping-cough, pulmonary inflammations, typhoid fever, or the previous existence of a chronic disease may be an antecedent factor. A few observers contend that some neuropathic condition is the cause of this dire disease. Some bacteriologists consider it the destruction wrought by certain cocci placed under the most favorable conditions. Although bacilli have been found that have been considered the cause of the disease, as yet the characteristic micro-organism has not been singled out. Cultures from the affected tissue of the patient under consideration were made and sent to a competent bacteriologist of this city, with the result that conspicuous among some of the nearly seventy micro-organisms that may inhabit the mouth were staphylococci and streptococci. This case certainly occurred without any infection from without. Her low state of vitality and poor hygienic surroundings unquestionably afforded a strange proclivity to the disease. She being poorly nourished, anæmic, and cachectic, but little resistance was given to the invasion of the causative germs, and they found in her tissues a favorable nidus to prosecute their work of destruction.

As to the pathology of noma, Forchheimer says: "We find all the evidences of a phlegmonous gangrene.

[1] Centralblatt für Chirurgie, 1892; American Journal of the Medical Sciences.

Surrounding the destroyed tissue there is an infiltrated zone. The latter is a true necrobiotic process, all evidences of cellular tissue being destroyed, only a homogenous substance, in which are found micrococci, being left. Around this is found connective tissue, the connective corpuscles being in active cell division, while the blood-vessels are closed by thrombi and lower forms of life. Outside of this we find healthy tissue. In every case of noma these four zones can be distinguished."

According to William Pepper, the pathological lesion in noma is first a bleb which attacks the mucous membrane of the cheek and adjacent gum. It is rarely bilateral. The bleb is so speedily transformed into an ulcer that it usually escapes notice. The lesion is corrugated and of a dark grayish hue, with sloughing surface. Coincidently the cheek becomes infiltrated and swollen. The ulceration next becomes gangrenous and spreads in all directions, and may perforate the cheek in from a day to a fortnight. The teeth loosen and drop out, while the tongue, palate, lips, eyes, nose, and ears may become involved. He explains that the non-occurrence of hemorrhage from such a lesion is due to the formation of thrombi which occlude the vessels in the surrounding infiltrated area. There appeared in the MEDICAL RECORD (1885, vol. xxvii., page 37) an article entitled "Contribution to the Pathology of Noma," written by Dr. Willard H. Morse. He reported a case of noma in which he made frequent and thorough microscopic examinations of the blood during life, and found "minute colorless bodies, highly refractile, of apparent crystalline consistency, in active and irregular movement." At a period when the blood seemed to swarm with these bodies a copious hemorrhage occurred, after which they were not seen in such relative frequency. He observed that previous to a hemorrhage there was in the blood an excess of white elements, the ratio being one to three of the red. After death he injected young rabbits with some of the diseased blood, and in three days an examination of fresh blood showed a vast number of translucent corpuscles. A second rabbit was similarly treated on the following day. An autopsy revealed distinct peritonitis and consolidated bases of both lungs. The peritoneal exudation showed vast numbers of white corpuscles, like those found in the blood. A young rat killed twelve hours after inoculation manifested an abundance of motile bodies in warm-drawn blood. Fluid from the wound was injected into the veins of rabbits and cats. Death resulted in a few hours from peritonitis. Froriep describes bodies resembling yeast bodies which he found in noma. Schimmelbusch found a pure culture on the border of the sound tissue, which he succeeded in cultivating on artificial media. Inoculation of rabbits caused œdematous swelling of the conjunctiva and keratitis.

The treatment of noma should be commenced in the initial stages to accomplish the best results. The mouth should be cleansed thoroughly and frequently with antiseptics and disinfectants; the patient should be stimulated freely. Intestinal antiseptics should be given to control the colitis that so frequently accompanies this disease. Fuming nitric acid, hydrochloric acid, chromic acid, and carbolic acid have each been applied as caustics, and have been strongly recommended by European physicians. Rotch, in his "Pediatrics" (page 790), says: "When the diagnosis has been definitely made, it is wiser not to temporize with applications of nitrate of silver and other drugs, but at once to place the case in the hands of a surgeon and have the entire area of the invaded tissues excised. It is also well after the gangrenous process has been removed by the knife to destroy an area of healthy tissue by means of the Paquelin thermo-cautery or by the galvano-cautery. There should be no delay in operating upon these cases, as great destruction of the tissues may take place in even a few hours. After the operation the tissues should be inspected frequently to see whether there is any return of the gangrenous tissue, and if found these spots should be removed immediately. As the disease is very apt to return, plastic operations to obviate deformity should not be undertaken very early after operation. In treating these cases surgically, it must be remembered that the child is in a very debilitated condition, and that if it is suffering from any special disease treatment directed to that disease is indicated; also that stimulants are required to prevent the already weakened child from dying from exhaustion following the operation."

Forchheimer, in the "American Text-Book of Diseases of Children," says: "It seems that the best and most active method of destroying this tissue is to be found in the use of the thermo-cautery of Paquelin or the galvano-cautery, and lately several cases have been reported in which success has followed these applications, although it is far too early to draw positive conclusions. As soon as the gangrenous nature of the disease has been established, the operation must be performed. A loss of time, even of hours, means considerable loss of tissue. The wound is to be treated according to surgical rules, and the plastic operations should be put off as long as possible, because in the first place they do not offer much chance of success when done early, and in the second place noma sometimes recurs as the result of these operations. In conclusion it must be stated that whatever has been done and will be done, the results must be bad, because the process is one developed in a patient very much reduced, in whom the least complication is likely to prove fatal."

In this case a radical operation would have been hazardous and was not considered expedient. Realizing in the case of my patient the condition of her already overwrought heart, her low vitality as a result thereof, it could not but appear that the flickering flame of life would have been the sooner extinguished through the exigencies incident to an operation.

SECONDARY HEMORRHAGE SUBSEQUENT TO TONSILLOTOMY.

By JOHN W. S. McCULLOUGH, M.D.,

ALLISTON, ONTARIO.

In the MEDICAL RECORD of August 29th last, Dr. F. A. Bottome, of New York, reports an interesting case of secondary hemorrhage following amputation of the tonsils, wherein the hemorrhage began sixty-six hours after operation. This, with the exception of St. Yves' case, which is an exceptional one, appears from the literature at my command to be the only one recorded in which the hemorrhage occurred at such a length of time following operation.

It is, no doubt, the experience of every operator in this class of work to encounter, sooner or later, this troublesome complication. Previous to my meeting with the case I am about to relate, I have not, in a list of about two hundred and seventy cases of operation for removal of the tonsils, seen a hemorrhage which was other than trifling, and I had almost come to regard it as unknown. I have changed my mind, however, and beg to relate shortly the history of a case of secondary hemorrhage following amputation of a tonsil, which occurred at a seventy-four hours' interval.

Mrs. L——, aged forty-nine, had her right tonsil and a small portion of the left one removed about three months ago. The hemorrhage was very small. She told me that the left one occasionally "swelled up," so I advised her to have the operation upon it re-

peated, in case it gave her any annoyance. At 12 noon of Tuesday, February 9th, she returned, and I found the gland in a state of acute inflammation (quinsy). I removed the pus-laden tonsil, and there was a trifling hemorrhage. On the following Friday evening she sent for me, and said that at 2 P.M. of that day she had spat up some blood, which continued to come more freely throughout the course of the afternoon. When I saw her there was free oozing from the cut surface. The clots were removed and the oozing part was cauterized with trichloracetic acid. This sufficed to stop the bleeding for a time, but it was again provoked by the patient's coughing. Astringents and caustics of various kinds were successively tried, without permanent avail, each fresh attack of coughing serving to induce the oozing. The patient had by this time lost about one and one-half quarts of blood, and, not being at all robust, was becoming very weak. I enjoined her not to speak at all, to avoid coughing as much as possible, and gave ice to suck. This very soon checked the bleeding, and was, perhaps, aided by my patient having an attack of vomiting, whereby she discharged a quantity of blood clots from the stomach, and at once collapsed for a few minutes. She rallied nicely, and without any further trouble recovered. The case was an alarming one, and I was seriously considering the possibility of having to ligate the carotid, when fortunately I thought of using ice.

I have been thinking of the possible cause in this case, and have come to the conclusion that it was undoubtedly the destructive action of the pus remaining in the wound. In future, when I amputate a purulent tonsil, I shall take the precaution of cauterizing the cut surface. In all my cases the Mathieu guillotine was the instrument used.

FOWL SERUM IN PNEUMONIA.

E. H. MARTIN, M.D.,

GREENE GROVE, MISS.

The fact that fowls are exempt from croupous pneumonia, and that they are not even inoculable with the germs, led me to a series of experiments in treating pneumonia with chicken and turkey blood. The experiments have now lasted a year, and, while my methods were crude and my cases few and unrecorded, I have had the pleasure of passing twelve months without losing a case of pneumonia. This may have been good luck, but I am inspired with faith enough to announce fowl serum as either a specific for pneumonia or else better than a rabbit's foot for luck.

My first case was of double pneumonia in a man, sixty years old, a very severe and distressing type. The patient lived eight miles from my office, and I saw him only twice. I employed the usual drugs, and, in addition, ordered two ounces of fresh chicken blood stirred into a half-teacup of hot water every four hours. Much to my surprise the man recovered, though anasarca was persistent for a month after recovery, showing how much the heart had been affected. Since then, case after case has done well under the treatment, and now the anxious mother whose son has pneumonia sighs more for her chickens than for her boy.

My excuse for publishing my conclusions before waiting for more extensive proof is twofold. First, to induce hospital experiments along the same line; and second, to induce some enterprising manufacturer to put a reliable fowl serum on the market. While the blood is not unpalatable—in fact, the patients learn to like it—the results from the injection of serum of a tested strength would evidently be more satisfactory and could be gauged intelligently. Then there is so little blood in a chicken, or even in a turkey, that the administration of the blood by the mouth is very expensive: and no one in country practice can experiment minutely with a case several miles away. The hospital ward, an undoubted case of lobar pneumonia, a good article of fowl serum, and the temperature chart would tell the rest.

So many die every year from this dread disease that I shall watch the columns of the medical press anxiously for the results of experimentation with fowl serum.

INTESTINAL OBSTRUCTION FROM FAULTY POSITION OF THE VERMIFORM APPENDIX.

By J. W. WRIGHT, M.D.,

BRIDGEPORT, CONN.

In Dennis' "System of Surgery," vol. iv., Dr. M. H. Richardson records three cases of intestinal obstruction due to faulty position of the vermiform appendix. I desire to add a fourth case of the same character.

A young woman, aged twenty-eight, after exercise on swinging-rings in the gymnasium, was seized with pains in the intestines, paroxysmal in character, and obstinate constipation November 13, 1896.

No relief being obtained from cathartics and enemas, I made an abdominal section in the median line. November 17th, and found a condition almost identical with that of Dr. Richardson. I ligated the appendix at its origin and distal end and removed it, reducing the strangulated ileum.

A small opening into the intestine, caused by traction on the appendix, was closed by a few Lembert sutures, and, the whole being replaced and flushed with sterilized water, the abdominal wound was closed. The patient recovered and resumed her duties as school teacher.

A CASE OF DILATATION OF THE STOMACH.

By A. S. HOTALING, M.D.,

RESIDENT PHYSICIAN, BAY VIEW HOSPITAL, BALTIMORE, MD.

Dilatation of the stomach is not uncommon, but a case of marked dilatation complicated by a contraction at the pyloric end, due to the cicatrization of an old ulcer, running its course almost to the termination without symptoms, is so unusual that it seems of interest to report the case. It is also of importance from the fact that at one time carcinoma of the stomach was diagnosed, owing to the seeming presence of nodules at the pyloric end which on palpation simulated a cancerous growth, but which simulation later on autopsy was found to be due to well-marked depression on the left lobe of the liver, corresponding to the ribs and due to pressure by them.

Mrs. L——, widow, multipara, aged sixty-three years, native of Ireland, was admitted to the medical ward, September 14, 1895.

Previous history: Her parents, so far as she knew, died of old age. Her children were all living. Except for the diseases incident to childhood, she had always been healthy until a few months prior to her admittance to the hospital.

On entrance she complained of paroxysmal pains in the chest, hacking cough, especially at night, dyspnœa, anorexia, night sweats, evening elevation of temperature with morning remissions, attacks of diarrhœa, and hæmoptysis. She was emaciated and very anæmic. The blood count at various times showed the red blood corpuscles ranging in number from 1,800,000 to 2,000,000 to the cubic millimetre. The leucocytes were about normal in number. Phthisis pulmonalis

was suspected, but a thorough physical examination at intervals revealed only a somewhat contracted hyperresonant chest, prolonged harsh expiratory murmur, and occasionally a few bubbling râles on the left side. The right lung and heart were normal. Numerous examinations of the sputum failed to show the bacilli of tuberculosis. The urine was normal.

At this time there were no marked indications of stomach trouble, and though the patient was seen by various members of the visiting staff, no diagnosis was made excepting emphysema and senility. Her symptoms did not ameliorate under treatment, and emaciation, cough, dyspnœa, and anorexia increased. Purgatives were always necessary for an action of the bowels. Blood was never noticed in the stools.

She remained in this condition until about two months previous to her death. At that time she began to complain of pain in the epigastric region, dull in character, ill-defined, and continuous, but which was not usually exaggerated on taking food. The epigastric region was occasionally tense, always tender on pressure. The tongue was furred, the stools were irregular, with eructations of gas and frequent severe headache. At times there were attacks of vomiting. The ejected matter, coffee-ground in character, was never large in amount, and the vomiting was not occasioned by food irritation. The ejected matter was never characteristic of gastrectasis, but was significant of carcinoma. Physical examination revealed a thin relaxed abdominal wall, with some bulging in the right hypochondriac region. Occasionally a peristaltic wave could be detected, especially on mechanical irritation. Percussion after one litre of water was administered showed the lower border of the stomach to be seven centimetres below the umbilicus. Owing to the marked asthenic condition of the patient, no attempt was made to distend the stomach artificially, and it may be stated here that this fact accounts for our not making an examination of the stomach contents. The patient's condition contraindicated any attempt to pass a stomach tube. On palpation, we found what we thought to be a mass of cancerous nodules at the pyloric end of the stomach, movable and slightly tender to the touch. The thin abdominal walls permitted palpation freely, and there seemed to be no ground for an error in diagnosis.

At this point the views expressed by Ewald[1] are of interest. "To distinguish a deformity on the lower border of the liver, especially in the left lobe, such as frequently results from tight lacing in women, or a true tumor of the liver, pancreas, or spleen, from a new growth in the stomach, may at times be very difficult, at other times impossible. The reverse may also occur: a carcinoma of the stomach may be regarded as belonging to the left lobe of the liver."

On auscultation, consecutive shocks by the hand produced the characteristic splashing sound heard in gastrectasis. The typical yellow hue of cancer cachexia was well marked. To reiterate, the patient, sixty-three years of age, presented the following symptoms significant of carcinoma of the stomach: belching, furred tongue, anorexia, pain increased on pressure, dull and continuous; periodical vomiting of decomposed blood, small in quantity; constipation, marked cachexia, tumor readily palpated and movable, complicated with signs of dilatation of the stomach. The diagnosis of carcinoma of the pyloric end of the stomach complicated with gastrectasis was made.

The patient gradually failed, and two weeks prior to her death would eat only when forced to do so by her nurse. Death occurred November 10, 1896.

Post-mortem, November 11th. All organs very anæmic. Stomach: length of lesser curvature, 21 cm.; length of greater curvature, 43 cm.; capacity, 1,800 c.c. The mucous membrane was congested. The walls of the stomach were not thickened, being unattended by hypertrophy. The lesion was situated on the posterior wall of the pyloric portion near the lesser curvature; it was oval in shape, five centimetres in diameter, and penetrated into the muscular layer. Its edges were thick and indurated, and the floor was smooth and pigmented. The pylorus had participated in the contraction following cicatrization, and its opening measured but six millimetres.

Portions of the ulcer were removed and hardened in Müller's solution. Microscopic examination showed the mucus membrane markedly infiltrated with leucocytes, the peptic cells being replaced by cylindrical epithelium. The submucous membrane was thickened with small-cell infiltration and new connective-tissue growth. The ulcer was completely limited from the surrounding mucous membrane by small-cell infiltration.

Liver: weight, 1,170 grams. The left lobe presented several depressions on its surface corresponding to the ribs. Macroscopically it presented the appearance of fatty degeneration.

Left lung: lower lobe emphysematous.

Other organs normal.

I am indebted to Dr. Julius Friedenwald, in whose service the case occurred, for his advice and interest in publishing this history.

[1] "Diseases of the Stomach," translation from second edition, Manges, p. 198.

HYSTERICAL AMBLYOPIA.[1]

By FRANK S. MILBURY, M.D.,

OPHTHALMOLOGIST AND OTOLOGIST TO THE BEDFORD DISPENSARY AND HOSPITAL, BROOKLYN, N. Y.

Hysterical amblyopia takes various forms, usually only a diminution in the acuity of vision, but sometimes complete blindness, even to loss of perception of light, defective central vision, with concentric contraction of the field, or with central scotoma. Color vision is often affected. Ophthalmoscopic appearances are normal. Little or nothing is known about the pathology of this affection.

In testing the vision with lenses, ophthalmoscope, or measuring the field, the nervous system becomes quickly exhausted, and the longer the examination continues the narrower the field becomes. A strange thing is that people thus affected move about with perfect security, which makes it difficult to ascertain whether there is simulation or not, unless there are other neurotic symptoms; but my experience has led me to the belief that it is found generally in persons of robust health in every particular. However, by careful investigation simulation may be eliminated.

Hysterical amblyopia is chiefly found in young girls; rarely in males. The prognosis is good, as in nearly all cases complete restitution takes place, but in some the affection may last for months or even years. Strychnine, iron, galvanism, etc., are among the agents used; but I think it is conceded that they have but little influence, except mentally, as in the so-called "faith cure."

In the last five years I have had in my private practice three such cases, in none of which was there any occasion to simulate.

Case I.—Young lady, aged twenty-two, from a Canadian city, was brought to my office by her father, in June, 1892. She had a letter to me from her family physician, stating that she had been completely blind for seven years, that her general health was perfect, that she had been treated by the best oculists of Paris and London, with no beneficial results, and that

[1] Read before the Long Island Medical Society of Brooklyn, January 5, 1897.

now she was taking a long sea voyage to South America, with the hope of benefit, and he incidentally asked her to call upon me, but not expecting that anything could be accomplished. As she was to be in Brooklyn several weeks, I concluded to examine the case and see what could be done. Her father told me that it had been diagnosed as hysterical blindness. I found no perception of light whatever and ophthalmoscopic appearances normal. I placed her on strychnine, iron, and galvanism. Hypnotism was tried by myself and others, but with negative effect.

In July the journey was continued, they going to Buenos Ayres, round the Horn, up the coast to San Francisco, and by rail to New York, arriving here in February, 1893, no better and more discouraged than ever, if that were possible. Something, I don't know what, induced me to look in her mouth; but there I found a badly broken-down second superior left bicuspid. Intentionally I enthusiastically exclaimed that I had found the cause of all her trouble. She doubtingly asked me "What?" and I told her that the disease of the tooth was in such a way connected with the eye as to produce pressure and thus caused blindness, and if removed would end her infirmity. As will be presumed, her faith was weak indeed, and it took many days and much talk to convince her that I was right. However, eventually she was convinced, and wanted it out at once; but I delayed several days for the purpose of having the fact fully impressed upon her mind. I had explained my scheme to the father, and he also built a big castle in the air in fear and trembling. At last it was concluded to extract the offending tooth. She wanted gas, but I told her that would in a measure destroy the effect, as the more it hurt her the better she would see. So out it came, and complete restoration of vision followed and remained normal until her death, which occurred in August, 1896, of typhoid fever, more than two years after the tooth was removed, and probably would have always remained so. It is somewhat strange that other means employed had not had the same effect. I wish it understood that the tooth had nothing to do with the loss of sight, and the extraction was merely a form of suggestion, which in her case worked all right, whereas in another similar case it might have had no effect.

Case II.—Boy, aged sixteen, very robust, suddenly developed blindness by playing baseball in a very bright sunlight. He immediately came under my care. The symptoms and the history appeared to point at once to hysterical blindness. The fundus showed no changes. Light and darkness were distinguishable, but that was all. Suggestion was tried, but with no benefit; then galvanism, injections of strychnine, etc., with the same negative results. Hypnotism was suggested to me by one of our leading neurologists, and tried by me. I got complete control of the patient in less than ten minutes. The fact that he would sleep and that his sight would be perfect when he awakened was kept prominently before him, and such proved to be the case. A few days later I examined his eyes carefully, but could find no refractive error. Two years have now passed by, and he remains all right.

Case III.—Edith J——, eight years of age, came to me on April 17, 1895, complaining of severe headaches and tired and smarting eyes. Her general condition was excellent. She had been seen by two ophthalmologists, the last prescribing — 0.75 D.S. over each eye. My examination found vision, R. and L., $\frac{6}{60}$ with + 0.25 D.S. = $\frac{6}{6}$ +; no astigmatism: exophoria, 1°; R. hyperphoria, 1°. Under atropine: vision, $\frac{6}{6}$ with + 2.00 D.S. = $\frac{6}{6}$ +, indicating a ciliary spasm. I prescribed for constant use + 0.75 D.S., continuing the mydriatic a short time. After return of accommodation I found vision with glasses still $\frac{6}{6}$ +. I saw her occasionally, and upon questioning found vision normal and no headache or asthenopia. I saw her last on January 28, 1896, when vision was $\frac{6}{6}$. On March 8, 1896, I was again consulted, this time the child stating that she could not read and that the headaches were intense. On testing then and many times subsequently I found it true, and that she was not simulating. She had sufficient sight to move around, but for no practical purpose, as she could not distinguish even large objects. I could get no improvement with glasses, and concluded that it was a severe case of ciliary spasm. So I atropinized, and even then could get no improvement. There being no retinal or nerve trouble, I concluded that I had a clear case of hysterical amblyopia. I at once tried hypnotism, but, she being a very self-willed child, I could not control her. I then resorted to the usual remedies, but with negative results. After a lapse of two months I suggested consultation, and my patient's father desired to have the opinion of Dr. Knapp. I gave him a minute history of the case, and he went over it very carefully, confirming my diagnosis that it was a case of hysterical amblyopia, and advised the usual remedies, with plenty of out-door exercise. His instructions were followed, but vision remained the same.

July 2d, the father wished the opinion of Dr. Webster, of New York. His was the same as that of Dr. Knapp and myself, and that in course of time she would recover, but perhaps it might be years. He suggested hypnotism, which I had already tried. I concluded to make another effort, and this time succeeded in getting her soundly to sleep in about seven minutes, all the time impressing upon her mind that she would see perfectly and have no more headaches. This proved to be true, and she still remains perfectly well. She was then under atropine, and with + 2.00 D.S. vision was full $\frac{6}{6}$. I prescribed these, allowing the mydriatic gradually to pass away. She is now wearing them with comfort. I think, as a general thing, in hypnosis nothing may be accomplished unless the hypnotic effect is profound.

215 Jefferson Avenue.

A CASE OF TUBO-UTERINE PREGNANCY.

By JOHN VASSALLI, M.D.,

Baltimore, Md.

Mrs. S——, forty-two years old, slender, of medium stature, has given birth to six living children and has had one miscarriage. On giving birth to her eighth child, adhesion of the placenta was observed, together with an enormous enlargement of the right tube, producing the effect of the presence of a second child lying with its back toward the right side, or in what is usually known as the second position. Upon detaching the placenta, the patient being under an anæsthetic, it became evident that the afterbirth was adherent, about one-fourth of its extent, to the inside of the right tube. The opening of the tube was about two inches in diameter, with hard and swollen edges, while the inner surface of the tube felt rough and uneven. It was strongly infiltrated, having a thickness of about two inches on the right (outer) side, while toward the inner side the growth was less thick. After removal of the placenta and irrigation with ice-cold solution of bichloride of mercury, 1–1,000, a rapid contraction of the womb took place. The tubal swelling remained perceptible to the same extent, but diminished daily, until on the sixth day it had entirely disappeared. The patient had no increase in temperature, and has now entirely recovered.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL SURGERY.

Stated Meeting, March 8, 1897.

W. W. Van Arsdale, M.D., Chairman.

Tuberculous Peritonitis; Operation; Recovery.—Dr. A. L. Fisk presented a man, over thirty years of age who had entered the hospital in November, 1896, with a history of gradually increasing size of the abdomen, some pain, and recently loss of flesh and strength. There was elevation of temperature, with evening rise to 103° F. Concluding that there was tuberculous trouble, Dr. Fisk opened the abdomen in the median line below the umbilicus, found the peritoneum thickened and studded with tubercles, the coils of intestine matted together, some fluid. Part of the wound healed by granulation. The temperature had returned to normal; the abdomen felt normal; the man had gained in flesh and strength.

Eucaine Anæsthesia in Herniotomy.—Dr. Howard Lilienthal presented a man, aged fifty-five, who had long had an irreducible hernia. It became strangulated, and he operated (owing to disease of the heart) under local anæsthesia by eucaine, aided by a little morphine. A further point of interest was the fact that the man left the hospital in two weeks with a clean scar, showing the advantage of closing the wound in the manner which he had practised in this and some other cases, by doing a Bassini operation with silkworm gut as suture up to the point of reaching the superficial fascia, but leaving this and the skin ununited, to heal by granulation.

Dislocation of Outer End of Clavicle.—Dr. Fisk presented an aged man, with dislocation of the outer end of the clavicle, which had occurred last July. The condition was rather rare, this being the first case which had come under his observation.

In the discussion on this case, Dr. Curtis said he had seen only about half a dozen cases of dislocation backward of the outer end of the clavicle, but none with the end of the clavicle so far backward. Usually the patients preferred to have nothing done. He supposed the clavicle could be wired to the scapula at its proper articulation.

Dr. John Erdman said he had seen a number of cases at Bellevue and other hospitals, not a few of them being recent cases, and good results had been obtained by reducing the dislocation and applying plaster splint.

Dr. Fisk said the great difficulty was in keeping the clavicle reduced, and some of the measures which had been suggested might, if successful in one direction, result injuriously in another—producing stiffness.

Dr. Van Arsdale had kept one case reduced by a tight figure-of-eight bandage.

Massage in the Treatment of Fractures.—Dr. George Woolsey read the paper. Until very recently less advance had been made in the treatment of fractures than in any other field of surgical practice. Comparatively recently the ambulatory treatment had received much attention. He had tried it in a number of cases, especially in fractures of the leg, and with considerable satisfaction. Under it the general condition of the body was maintained, and it was especially useful in the aged and alcoholic, in that it shortened their stay abed. It prevented stiffness of joints, allowed the patient to go to business, and cleared the hospital wards. It did not shorten the period of healing. Keeping the patient abed, as was done under the rest-and-fixation treatment, had an ill effect upon the health and weakened the muscles. These objections were overcome by massage treatment. Dr. Woolsey, in presenting the claims for this method, quoted freely from Championnière, its champion. Among the effects of massage were the relief of pain, diminution of swelling: secondary œdema, which under other treatment often came on after five or six weeks, was conspicuous by its absence: the muscles were kept from atrophy, the skin remained soft: the callus was stronger, the general health was maintained. When there was great mobility, immobilization could be applied until consolidation began; then massage should be commenced. In other cases massage could begin at once, and if a splint was applied it could be removed during massage once daily. Massage should be practised in the direction of the return blood current, superficially with the whole hand, or deeply with the thumb and finger, with light movements which would relieve, not cause, pain and reduce the swelling. The best lubricant was olive oil. The duration of the *séances* was fifteen minutes. The treatment was more especially indicated in fractures near joints. Dr. Woolsey had begun treatment by massage rather cautiously a year ago, and had not allowed his patients to get up quite so early as do French and German surgeons. Most of his cases had been Pott's fracture, some of Colles', etc. One writer had had considerable experience with combined ambulatory and massage treatment, and considered it ideal. Dr. Woolsey's own results from massage had been so perfect that he had come to make it the routine treatment in fractures near joints. Bony union was obtained by the end of the third week. The patient was allowed to get up from the nineteenth to the twenty-fifth day, and within two or three days was able to walk about without a cane. The average stay in the hospital had been twenty-one days. Massage treatment was recommended by the author in fractures near joints, to be applied daily for fifteen minutes until consolidation occurred, say the first ten days. In fracture near the middle of the limb, he would immobilize and then let the patient go about on crutches—the ambulatory treatment; and carry out the same treatment in fracture of the neck of the femur in the aged.

Dr. Howard Lilienthal said he had employed the massage treatment in three cases of fracture of the patella, with excellent result. All the patients were kept walking after the tenth day.

Dr. A. E. Gallant testified to the excellent results of massage in the treatment of sprains, and he had no doubt it would be equally efficacious in reducing swelling and pain in fractures. Under the teaching of Dr. Van Arsdale he had learned to employ it from the moment that sprain occurred, commencing far above the sprain, rubbing the limb gently at first and toward the body, gradually reaching the injured joint and rubbing along the grooves instead of on the bones.

Strangulated Hernia in a Child of Four Months: Operation; Recovery.—Dr. Charles N. Dowd read a brief paper on strangulated hernia in infants, and reported a case in a child aged four months. There had been no evidence of hernia the previous day. He saw the child after strangulation had existed six hours. The tumor was as large as a goose's egg. Taxis having already been tried under ether, he performed Bassini's operation at once. An interesting feature of the operation was the excellent way in which the baby endured the ordeal, which lasted three-quarters of an hour. Healing was primary, and that side of the abdomen seemed at present as strong as the other. Strangulated hernia in babies was very rare. In his opinion there should be only one light effort at taxis, and that failing, radical operation ought to be per

formed. He had collected thirteen cases placed on record since 1894, all of which had resulted in recovery.

Dr. B. F. Curtis mentioned a fatal case of strangulated hernia in a baby. A part of the bowel looked almost gangrenous, and it was not returned to the abdomen for some hours, but was wrapped in towels wet with hot salt solution. Peritonitis caused death.

Case of Septicæmia; Recovery after Use of Streptococcus Antitoxin.—Dr. Howard Lilienthal reported the case. Before it was brought to the hospital it had been treated as one of supposed rheumatism of the thigh, and later the doctor had made a diagnosis of some bone affection. There was no clear history of septic infection, but the clinical course throughout was one of intense septic infection, with for days more or less coma, icterus, great pain, *cri encéphalique*, partial suppression of urine, fever, etc. The femur was diseased; the periosteum was easily lifted; there was no pus in the bony canal, but an abnormal amount of fat. The knee-joint, not being positively involved, was not interfered with. The wound was packed with gauze containing little iodoform. Some days later an abscess cavity was opened in the thigh, and streptococci were found. When Dr. Gerster saw the patient he advised against further operative interference, as the patient seemed moribund and would probably die on the operating-table. Having seen good results from streptococcus antitoxin in two other cases, he decided to try it in this, with the result that after some days the child showed decided improvement and went on to final recovery. Several doses of the antitoxin, Gibier's, were administered, usually eight cubic centimetres. Dr. Lilienthal said it was possible the patient would have recovered without the injections, but he thought not.

Dr. Richards reported a case of puerperal septicæmia in a patient attended by a midwife, and later seen in consultation with him by Dr. Mundé and others; prognosis very bad. Having previously cleansed out uterus, he decided to try streptococcus antitoxin. The the patient made no improvement under one brand, but showed rapid improvement and recovered under another.

Dr. A. G. Gerster fully corroborated all that Dr. Lilienthal had said with regard to his case. He regarded the recovery as little short of marvellous. The extreme rigidity and dilatation of the pupil, the unconsciousness, and peculiar cry led him to suspect encephalitis. Under the encouragement of this experience, he had been led to employ streptococcus antitoxin in several cases at Mt. Sinai. The first was the case of a boy with very acute infectious osteo-myelitis of the femur. On chiselling into the bone, it was found literally honeycombed, and in former days, when he was a student under Rokitanski, would have been treated by amputation of the limb. General sepsis was manifest from the development of subcutaneous abscesses in different parts of the body. The pus was found to contain the yellow staphylococcus. Albumin appeared in the urine. On using streptococcus antitoxin the patient began to improve at once, and was soon in condition admitting of amputation, which previously had been rejected by the parents. The boy recovered. The next case was one in which there were distention of the gall bladder, peritonitis, general sepsis. Dr. Van Arsdale had operated for him. Streptococcus antitoxin was used, and the patient recovered. In another case, one of appendicitis, peritonitis, and general sepsis, the antitoxin was used; the patient recovered. In a case of puerperal sepsis, the large joints involved being distended with fluid, the patient was sent to the hospital, with the expectation that she would die; but after the antitoxin was given, she began to improve and was still improving. Dr. Gerster then related a case of sepsis in which the serum failed and the patient died. While the favorable cases seemed to point to the value of the streptococcus antitoxin, still we should not come to too hasty a conclusion, for we knew that now and then patients recovered from general sepsis without such treatment, when recovery seemed impossible.

Amputation at Shoulder for Sarcoma of the Arm.—Dr. Fisk presented a woman, sixty-seven years of age, whom he had presented at the meeting in December with *x*-ray photograph showing a tumor of the humerus, the diagnosis at that time between possible fracture with callus and sarcoma not being positive. Some tissue removed under exploratory incision was proven on microscopical examination to be sarcoma, and he amputated at the shoulder. The wound healed primarily.

Dr. Torek presented a specimen of sarcoma of the arm in a boy, which had led him to perform amputation at the shoulder, with entirely satisfactory result. The interest in the case was the fact that there had been fracture, and the probability was that the sarcoma had developed afterward, although it was possible that in this case as in many others the disease had been present before, and without it fracture would not have occurred. He mentioned the case of a woman who had sarcoma of the arm, fractured the limb while lying abed, and he amputated at the shoulder. In the case of the boy the first specimen of tissue removed was pronounced by the pathologist to be only granulation tissue, but the subsequent development of the tumor made it positive that there was sarcoma, and led to amputation.

When Shall We Operate for Cholelithiasis?—Dr. Carl Beck read a part of his paper with this title. There was no doubt that many patients with cholelithiasis were relieved by a course at Carlsbad, and it was interesting to read Kocher's account of the relief which he had himself thus obtained from symptoms for which he had often operated upon other patients. In summing up, Dr. Beck said it was not easy to arrive at a distinct understanding regarding operative and non-operative cases. Yet we already had a certain basis for the selection of cases in which medicinal treatment should be given a thorough trial, and by exercising due discretion the cases would become fewer in which relief would be thus obtained after the surgeon had said positively that an operation alone could save the patient. Certain dangers, relating to perforation, etc., had to be borne in mind as liable to occur in any case. While, then, in certain cases the operation was clearly indicated, in others much judgment was required in answering the question in the best interests of the patient.

Dr. John Erdman quoted, as expressing his own views, the five indications given by Gersuny, essentially as follows: Danger of rupture by overdistention of the gall bladder, either by the stones or accumulation of fluid; danger of sepsis, or beginning sepsis with empyema of gall bladder; frequent attacks of colic; frequent recurring attacks of jaundice; frequent recurring attacks of pain, which laid the patient up.

Swellings of the Neck.—Swellings of the whole neck are common; their causes are numerous; they may follow injuries, inflammations, tumors, operations. Their common feature is a great danger from the propagation to the aryteno-epiglottic folds, causing obstruction of the larynx and pressure symptoms, specially dyspnœa, which it is often impossible to relieve because of the difficulty of reaching the trachea. If an attempt is deemed justifiable, the operator should be provided with an extra long tracheal cannula.—Souchon.

Therapeutic Hints.

Gallic Acid.—Dr. Freer has found this a valuable hæmostatic and remedy for purpura, intestinal hemorrhage, etc. He gives from five to twenty grains at bedtime or oftener.

Yellow Fever.—Tincture of eucalyptus in large quantities attenuates the severer symptoms. Thirty to forty grains can be given in twenty-four hours. Frequent enemas of water, containing thirty grains to the quart, are advised.—*Tribuna Medica*, No. 10, 1896.

Tasteless Dextro-Quinine.—

℞ Dextro-quininæ ..... ʒ i. to ʒ ij.
Pulv. aromat. ..... ʒ ij.
Pulv. ext. glycyrrh. ..... ʒ ij.
Ammonii carbonat. ..... gr. xv.
M. ft. pulv.

Formic Aldehyde is recommended by Dr. Salter (*British Medical Journal*, September 12, 1896) as an application in trichophytosis capitis, because of its penetrating qualities. Either formaldehyde of English manufacture or Schering's formaline in forty-per-cent. solution was employed. It may cause swelling of the face.

Pills of quinine that have been made for some weeks or months, sugar-coated pills, old gelatin-coated pills, and quinine in capsules should be avoided, because of the uncertainty as to their solution.

Malaria.—In patients suffering from gastric catarrh or the gastro-hepatic symptoms of lithæmia, it is often desirable to precede the specific treatment of malaria by a short course of broken doses of calomel, and it may be necessary to give quinine by suppository or subcutaneously.—Daland.

Nervous Insomnia.—

℞ Formamidate of chloral ..... 10 gm.
Tincture of ginger ..... 10 "
Distilled peppermint water ..... 150 "
M. S. A dessertspoonful at night.

—Boas.

Pertussis.—Inhalations of ozone, two to four times daily, for from ten to fifteen minutes each time.—Labbé *and* Oudin.

Phthisis.—Creosote is recognized as the most efficient agent we possess for the treatment of tuberculosis, but being caustic it can be given only in small doses. This objection does not hold for "creosotal" and carbonate of guaiacol. The creosote in it is in such combination that doses formerly believed impossible can be administered; hence their administration constitutes a most important advance in the treatment of tuberculosis. As creosote is not better borne in any other form, "creosotal" and carbonate of guaiacol are to be preferred in all respects in the treatment of phthisical cases.—Dujardin-Beaumetz, *Dict. de Thérap.*

Bone Marrow in glycerin extract was given in doses of from one-half to one and one-half drachms, three times daily after food, up to four ounces weekly, in a case of pronounced osteomalacia, by Dr. T. M. Alliston.—*Edinburgh Medical Journal*, May, 1896.

For Rapid-Dispensing Salicylate-of-Sodium Mixture.—

℞ Salicylic acid ..... ʒ ij.
Sodium bicarbonate ..... ʒ ix. gr. xv.
Tincture of cardamom ..... ʒ i.
Glycerin ..... ʒ ij.
Water enough to make ..... ʒ xvi.

In an open-mouthed vessel of the capacity of four pints, stir the acid with sufficient water to form a pasty mass. Then add the bicarbonate and stir vigorously until the effervescence has begun to cease. After the foam has settled, strain the solution, add the glycerin and cardamom, which have been previously mixed, and filter the product through a plug of absorbent cotton, finally adding enough water to make the preparation measure sixteen ounces.—H. B. Mason, *The Druggists' Circular and Chemical Gazette*, February, 1897.

Pruritus Pudendorum.—Apply each night, after a disinfecting vaginal injection, compresses wet with a hot solution of tannic acid (tablespoonful to the quart).—Heidenhain.

Test for Tincture of Iodine.—Having observed vomiting after injection of tincture of iodine into the uterine cavity, Dr. Blondel (*Gaz. des Hôp.*, February 4th) attributed it to the presence of hydriodic acid. The presence of this acid, which is apt to develop in tincture which has become old, is detected by the fact that the iodine is no longer precipitated by the addition of water.

Chorea.—Arsenic in large and progressive doses. One centigram from the first day, increased each day half a centigram up to four centigrams, in plenty of water or mucilaginous menstruum. Repose in bed: milk diet. Having reached a daily dose of four centigrams, run down the scale in the same way and stop. Cure in eight days.—Comby, *La Méd. Normandie*, February 1st.

Carrot Juice, in dose of fifty to one hundred and fifty grams, slightly salted, is recommended in impetigo of infancy, and it is thought may be of use in tuberculosis.—Artault.

Insufflations into the nasal fossæ five times daily of

℞ Powdered benzoin,
Bismuth salicylate ..... āā 10
Quinine sulphate 2

produce rapid improvement in pertussis.—Moizard.

Boric Acid in four-per-cent. strength, used in quantities of two litres as douche, caused vomiting, pains, fever, albuminuria, borin in the urine. Recovery.—Forneaux, *Jour. des Sci. Méd. de Lille*, July 18, 1896.

Puerperal Eclampsia and Milk Diet.—I see that Professor Lusk advocates a milk diet for pregnant women, and am just here reminded that the milk diet becomes a veritable hobby with many people, which may be excusable in the great centres of population where milk is a luxury, but half the women in this great State of Ohio would rather take the risks of a siege of eclampsia than to be tortured for three months upon a milk diet. But our study of the etiology indicates the necessity of a diet restricted in quantity generally, in the absence of a knowledge of the specific poison or its composition; and, when the usual prodromal symptoms put in an appearance, a diet of any kind should be interdicted until the natural and usual medical means of eliminations have had time to rid the system of its baneful products.—W. S. Philips, *Columbus Medical Journal*, January 19, 1897.

Potassium Iodide is badly tolerated in some instances of hepatic disease. The sodium salt may prepare such patients, as well as those in whom depressing effects result from the potassium iodide, for the subsequent favorable use of the latter.—Briquet.

Arsenite of Sodium is said to be the best form in which to administer the drug hypodermatically, not producing toxic effects so quickly as when arsenic is given by the mouth.

Anaphrodisia may be produced by the prolonged use of arsenical preparations.—Charcot.

Pain following burning accidents is said to be quickly relieved by immersing the part in water in which a few spoonfuls of saltpetre have been dissolved.

Hæmoptysis in Infants.—

℞ Pulv. aluminis ..... 0.05 cgm.
Mist. sulphuricæ acidæ (eau de Rabel).... 20 gtt.
Ext. krameriæ fld. ..... 2 gm.
Syr. rosæ..... 60 gm.
Aquæ dest..... 160 gm.
S. From a teaspoonful to a dessertspoonful every half-hour.

—Cadet de Gassicourt.

Phthisis.—In the attacks of coughing:

℞ Bromoform..... 30 gtt.
Alcohol..... 10 gm.
Syr. ipecac..... 30 gm.
Aq. laurocerasi ..... 20 gm.
Syr. opii (Fr. cod.).. .....150 gm.
S. Three or four soupspoonfuls in twenty-four hours.

—*Gaz. des Hôp.*

Thyroid Medication in Infancy.—Tablets containing thirty-five centigrams of the active substance may be given to infants, one-half to one tablet being the daily dose during the first week in infants below the age of two years. After this, one or two tablets daily may be given. During treatment, loss of flesh, tachycardia without palpitations, and increased thirst and diuresis are among the symptoms noted. In parenchymatous goitre the remedy produced rapid regression of the tumor, the maximum decrease in size being manifest at the end of the third week of administration.—Dobrowsky, *Vratch*, No. 27, 1896.

Bronchitis.—

℞ Acidi benzoici..... 0.3 dgm.
Tannin..... 0.15 cgm.
For one powder—four such daily.

—Maragliano.

Benzo-Iodhydrin, a solid, fatty, crystalline body, containing iodine, chlorine, and benzoic acid, has been employed by Barth as a substitute for the iodide of potassium. It produces no iodism, and does not exert the same influence upon blood pressure producing congestions. It, however, cannot replace the latter drug in the treatment of syphilis. It appears indicated whenever the myocardium is affected, favoring a considerable determination of blood to that organ. In degeneration of the myocardium and coronary sclerosis, the action is favorable. All affections associated with arterial hypertension, arterio-sclerosis, atheroma, etc., justify the use of this remedy.—*Journal des Praticiens*, January 2d.

Iodide of Potassium Pills.—The following procedure is recommended by Duyk for the preparation of iodide pills which will keep for some time: Iodide of potassium, gram 7.70, is triturated with gum benzoin, gram 2.30, and converted into a pill mass with the aid of a few drops of alcohol. This is divided into one hundred pills, of ten centigrams each. According to the author, these are readily dissolved in the fluid of the stomach. Another plan, suggested by Lang, is to triturate twenty grams of the iodide with ten grams of sugar of milk, to which six grams of lanolin is then added, to make one hundred pills. It is claimed that the iodide in this form is but little irritating.—*Le Scalpel.*

Digitalis in Pneumonia.—Barth doubts whether the enormous doses given by Petrescu are free from risk, and whether the artificial lowering of temperature by them is of real value: forty-five grains a day of the powdered leaves should be the maximum dose.

Uterine Disease.—Irregular menstruation with retroflexion, parametritis, etc., was benefited by liquid ovarin, which is a glycerin extract of ovaries of young cows, containing one gram of ovarian tissue in half a gram of glycerin, injected into the buttocks daily in doses of half a gram to one gram. Compressed tabloids, containing 0.25 or 0.30 centigram of dried gland, proved quite as efficacious as the injections, when two or three a day were given, and were adopted finally in place of the injections. The treatment can be continued for a month or more, and is always well borne.—Muret, *Rev. Méd. de la Suisse Rom.*

Gumma of the Ciliary Region.—Treatment consisted of the administration of one-fourth of a grain of calomel combined with opium every three hours. When the gums began to show signs of approaching salivation, the dose was reduced to half a grain of calomel *per diem*. A fortnight later the iodide of potassium was commenced, in addition to the calomel. Locally, belladonna fomentations and atropine drops were employed throughout the first few weeks. In the course of a month, however, when it was found that the tension was remaining high and that the bulging of the staphylomata was increasing, eserine was used in place of atropine, and a compress and roller bandage were firmly applied. This soon reduced the tension, and the staphylomata ceased to enlarge.—Highet, *British Medical Journal*, November 7, 1896.

Seasickness.—

℞ Chloroformi puri,
Tinct. nucis vomicæ ....āā 10 gtt.
Tinct. lavandulæ comp ..... 4 gm.
Aquæ..... 35 gm.
M. S. Teaspoonful every hour until cessation of vomiting.

—Barber.

Epilepsy, with Maniacal Excitation.—

℞ Potass. brom.. ..... 70 gm.
Pilocarpinæ nitrat.. ..... 0.035 mgm.
Syr. aurantii cort. amar. ..... 400 gm.
Aquæ ..... 600 gm.

Each teaspoonful contains half a milligram of pilocarpine, under whose influence the maniacal excitation disappears.—Voisin.

Septic Endocarditis.—

℞ Quin. hydrochlor. ..... 5 gm.
Hg. bichlorid!.... ..... 0.20 cgm.
Pulv. althææ.... ..... q.s.
For 20 pills. S. One three times daily.

Oxyuris Vermicularis.—The threadworm of children is treated by Comby as follows:

Santonin..... 0.15 cgm
Calomel ..... 0.15 cgm.

One such powder is given each morning before food for three consecutive days, and for the three following days at bedtime an intra-anal application of the following ointment:

Glycerole of starch ..... 20 gm.
Neopolitan ointment.. ..... 10 gm.

Cancer of Stomach.—In the vomiting of this affection Robin prescribes from five to eight drops of the following solution, to be taken from five to ten minutes before each meal:

℞ Picrotoxin,
Hydrochlorate of morphine ..... āā 0.05 cgm.
Neutral sulphate of atropine..... 0.01 cgm.
Aq. laurocerasi ..... 10 gm.

Tabes.—For the gastric crises, oxalate of cerium, from five to fifteen centigrams, four times daily. Pain, thirst, nausea, and insomnia gradually disappear, and vomiting is reduced to a minimum.—Ostankoff.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

COMING AGITATIONS—VENEREAL DISEASE AND REGULATIONS — VACCINATION — VORACIOUS HUNGER AND THIRST—TRAUMATIC NEURASTHENIA—THE CYSTOSCOPE AS A GUIDE TO RENAL DISEASE—GYNÆCOLOGY IN RELATION TO SURGERY.

LONDON, February 26, 1897.

We are threatened with another agitation on the contagious diseases acts. As I stated last week, the fact that there is a large increase in venereal disease among our troops in India is now admitted, and some sensational statements have been circulated. In the House of Commons the government has since stated that the report of the departmental committee on the subject will be ready "in a few days." Its issue will doubtless be the signal for heated discussion. Meantime, Major-General Dashwood has read a paper at the United Service Institution, in which he embodied some startling statistics on the health of the troops in India and the colonies. In the discussion that ensued several medical and combatant officers joined, and no little animation was manifested. Admiral Kennedy said that on one occasion his attention was called to the health of his own ship, and he found that out of thirty-eight cases of illness no less than thirty-six were venereal. One medical officer with thirty years' service in India, and another with still longer experience, advocated some sort of regulation as necessary, and they were supported by others who had witnessed the working of the acts and testified to their value. On the other side were ranged several well-known opponents of restriction, who maintained that a return to the acts would be impossible, and evinced a determination to oppose such action tooth and nail.

It was proposed to form a committee to agitate in favor of restriction, but the suggestion was not adopted, in the hope that this meeting and the coming report would suffice to induce the government to take some action. There seems to be a notion entertained by a large number that the present ministry is inclined to such action. If so, it had better move quickly, or it will find its opponents actively organizing against it, and the public will soon forget the disclosures which have produced an impression that "something ought to be done."

Vaccination is another subject that threatens us again. Before the Statistical Society Mr. Noel Humphreys and before the Epidemiological Society Dr. McVail have read able papers, and the Society of Medical Officers of Health have considered the report of the royal commission. This report came in for shrewd criticism in each of these societies, and the only part giving any satisfaction was the recommendation to promote revaccination. This seems now the point on which to insist, as the one on which our legislators will be most ready to act. But it need not be supposed that the "antis" will awake to reason, when Gloucester has taught them nothing.

Time and space being restricted, I was obliged to omit in my notice of the last Clinical Society's meeting an account of Mr. Stephen Paget's paper on "Voracious Hunger and Thirst after Injury or Disease of the Brain." But the facts collected by Mr. Paget are of a very interesting kind, and the association he has observed between morbid sensations of appetite and brain lesions may lead to further light in a rather dark field of inquiry. He thought his facts pointed to the existence of special centres of hunger and thirst close to the centres of speech, probably in the anterior extremity of the temporo-sphenoidal lobe, near the uncinate gyrus.

Mr. Paget had collected fourteen cases, one having occurred in his own practice, in which a lesion in this part had been followed by intense hunger and thirst. Eleven of the cases were of injury: three of disease. Eight of the fourteen subjects had voracious appetite for solid food, without much thirst; three had intense thirst without hunger; the other three suffered from both hunger and thirst. In none was the primary lesion fatal, so the centres were not situated near the vital centres. Three had aphasia. It was therefore probable that the centres were near to those of speech, and perhaps they were connected with the olfactory centre. The inordinate desire for food and drink lasted, as a rule, for many weeks or months, and then came to an end. It was not connected with mental derangement or traumatic diabetes. No harm came from indulging the desire.

In the course of the discussion three other cases were mentioned, in each of which there was abscess of the temporo-sphenoidal lobe. In one subject who died the whole lobe was found to be an abscess cavity, in which no centres could remain. It was further suggested that the symptoms might be due to shock of the whole brain, voracity being common after an epileptic fit, though it soon passed off, while loss of memory is also found for a short time after a fit, but may last a long time after severe injury.

The president, Dr. Buzzard, could not call to mind such striking examples. Physicians are likely not to see what they do not look for, but now they would be looking out for the symptoms and would probably find them. He thought there was ground for locating the centres of hunger and thirst as proposed. The phenomena would probably be produced through the vagus and its cerebral roots, and those roots may be in the temporo-sphenoidal lobe, for their exact site is not known. Ravenous hunger sometimes immediately follows the gastric crises of Charcot's disease.

On Monday an interesting paper on "Traumatic Neurasthenia" was read at the Medical Society meeting, by Mr. Victor Horsley. He thinks these cases do not essentially differ from those of neurasthenia brought on by worry or overwork. In acute cases there is a neurotic temperature, the rise being considerable, and in one case it reached 111° F. The patient is hindered from intellectual work from inability to concentrate his attention. General paresis or localized paralyses are observed, or there may be spasms and muscular twitchings, or again paræsthesia or anæsthesia. Superficial and deep reflexes are alike diminished, and eventually absent. Frequent micturition is troublesome. The urine is pale and the solid ingredients are lessened, but this is only proportionate to the increased secretion of fluid. Palpitation is not uncommon. Asthenopia, indicating the commencement of impairment of vision, is frequent, but other disturbances of the senses are rare, though subjective tactile sensations may sometimes be complained of. As all the symptoms can be explained on the assumption of some general disturbance of the central nervous system, it was suggested that in legal cases the medical witnesses on both sides should meet in consultation before going into court—a suggestion, I may remark, made on every suitable occasion during the last few years, but which has hitherto been unproductive.

Mr. H. Fenwick read notes of twenty-one cases, in which the cystoscope had been found of great value in detecting malignant or tuberculous disease of the kidney, and so serving as a guide to nephrectomy. The great advantage of an early diagnosis is undeniable, and was illustrated by Mr. Fenwick.

Mr. Lockwood admitted the value of the cystoscope in diagnosis, and said the instrument is coming into

use among general surgeons just as did the ophthalmoscope, and he had himself found it useful in several cases, of which he gave some account.

The new president of the Gynæcological Society is Mr. Mayo Robson, and he has followed up his predecessor's address in one which is equally favorable to the antiseptic system, though from a different point of view. His topic was naturally gynæcology in its relation to surgery. Referring to the "time when that most successful operation, ovariotomy, was considered ruthless slaughter," he said the change was so great in so short a time that we might almost call it the "renaissance of gynæcology," and the chief reason of the great reformation and all-round improvement of surgery he attributed to the "genius of our fellow-countryman, Lord Lister, whom all the world delights to honor."

OUR PARIS LETTER.

(From our Special Correspondent.)

HEALTH OF PARIS—LA GRIPPE—PREMATURE-BURIAL SCARE—THE INTERNATIONAL SANITARY CONFERENCE—CONTAMINATED MEAT, ETC.

PARIS, March 3, 1897.

THE health of Paris at this season of the year is about the average in others, excepting those years when we have had epidemics of grippe. There are, it is true, many cases of grippe just now; in fact, the tendency to increase in the number of such cases began the latter part of December. These cases, however, are mostly of light character, complicated sometimes with bronchitis confined to the larger bronchial tubes; rarely with capillary bronchitis or pneumonia. The latter, when we have it in Paris, is altogether less mortal than in the United States. The forms of grippe that we have at present are three in number, viz., the gastric form, the nervous form, and the catarrhal form. The latter is by far the most common. The diagnosis of grippe is not always easy, and in those obscure cases in which we have, so to speak, to feel our way, if antipyrin be prescribed the patient will generally respond at once to the treatment and there will be no further difficulty in the subsequent management of the case. As a rule, ten grains four times a day will be found sufficient: this treatment we supplement in Paris, when there is even moderate fever, with four grains of the bromhydrate of quinine morning and evening. The diet should be strengthening; also wine and stimulants be allowed—that is, more especially in the catarrhal and the gastric forms, but caution must be observed in their use in the nervous forms of grippe. Antipyrin, quinine, and the bromides are our sheet anchors in this form of grippe. Antipyrin must always be given in every form of grippe. After many years' experience with this drug, we have never known it to produce the deleterious effects sometimes attributed to its exhibition; in pure grippe never. In two cases, however, of neurasthenia and in the doses mentioned above, which are moderate ones, it did produce a slight mental and physical depression, which passed off as soon as the antipyrin was stopped.

Paris has just been through what may be appropriately termed the burial-alive scare. Owing to unfortunate publications in some of the daily newspapers of grewsome stories about people turning in coffins, laceration, etc., the Parisians became alarmed and much exercised on the subject of premature burial. The scare also made itself felt to some extent in England and the United States as well. We took the trouble to ascertain the views of all the leading physicians and authorities in the matter, residing and practising in Paris. Among those consulted were, first, the four leading American physicians — Drs. Good, Clarke, Halsted Boyland, and Austin. These gentlemen were unanimous in their opinions. None of them had ever known or heard of a duly authenticated case of burial alive, and considered the accounts of such occurrences totally unworthy of credence or even serious attention.

Such also was the opinion of most of the French experts, and among them Professors Brouardel, Proust, Potain, Dieulafoy, Drs. Labadie-Lagrave, Huchard, and Duguet.

Dr. Vibert, legal expert to the courts of Paris, was of the same opinion.

The outcome of it all was that the public became reassured and the subject has been dropped for about ten years to come, when, experts say, we may expect a revival of it, as it is fortunately only in decades that people become possessed of the idea that there is danger of being buried alive.

Professors Brouardel and Proust have left Paris for the International Sanitary Conference, now in session at Venice. The United States' technical delegate to this conference is Dr. H. D. Geddings, surgeon in the navy and well known by his works in the field of bacteriology. The object of the conference is to devise the best means of preventing the bubonic pest, now raging with a high mortality in Bombay, from entering into Europe. The last Dresden and Paris conferences were held with reference to the importation of Asiatic cholera, and the present one is to see if the measures then adopted cannot now be applied to the bubonic pest. Another of the objects of the present conference is to stop the pilgrimage to Mecca—a fruitful source of spreading both cholera and plague. This has been done.

The question of infection by contaminated meat has been very forcibly brought to notice again. Professor Pouchet's report on the subject to the Society of Legal Medicine is well worthy of attention. He says the medico-legal examinations of contaminated meat remain generally negative, and it is only the bacteriological examination that can give real data regarding the nature of an epidemic. It appears that in several communes in the Departement du Nord there were quite recently some fifty persons ill and one death from a disease attributed by the local doctor to contaminated pork.

Dr. Pouchet examined samples of this meat; also the dejections of two patients. Although he found a total absence of any toxic substance—vegetable, animal, or mineral—he was nevertheless able to isolate a special bacterium, that upon a microscopical examination and cultures proved to be none other than the specific bacillus of infectious porcine pneumo-enteritis. This bacillus was not found, it is true, in the fæcal matters; nevertheless, Dr. Pouchet noted the presence of the bacterium coli, whose virulence had become much increased. The matter was cleared up at once, when it was known that just at that moment hog cholera was prevalent in the communes where these cases had occurred. A raiser and dealer had not long before sold fifty-seven hogs, of which forty-seven had died of the disease. In the second place, the meat, too much damaged to sell, instead of having been burned or buried with quicklime thrown upon it, as should have been done, had been simply buried level with the ground; finally, no precaution whatever had been taken to separate the healthy from the diseased animals. Such a thing could not have occurred in or near Paris, or any large city, and it only shows that in districts remote from them the sanitary precautions are not well and efficiently carried out.

THE DISPENSARY ABUSE.

To the Editor of the Medical Record

Sir: Having read your articles on hospital and dispensary abuses, also reports on the same of the New York County Medical Association, 23d ult., I would offer a few suggestions which can be put into immediate practical use toward lessening the evil while awaiting the development of some scheme of greater utility and value.

1st. It is an acknowledged fact that all physicians seeking or holding dispensary appointments at the present time aim to become acquainted among the ailing community in which they reside, and financially to benefit by the doubtful prestige which official connection with public institutions imparts in the public mind.

2d. The executive authorities in those institutions amiably recognize this weakness, and while they fix their eyes on some far distant realization of spiritual renovation, whose absence they are destined so constantly to bewail, stand firm in declaring that the advertising privileges accorded fully remunerate physicians for any and all services rendered.

3d. These advertising privileges consist of permission to have inscribed or printed on a patient's card or passport, the attending physician's name, address, office hours, connection with institution, etc.

4th. Now, if the various medical societies and physicians will make the effort to help themselves, they will command greater attention when seeking help from others; and I would suggest their enjoining any practitioner who desires to remain in good standing from having his or her name, address, office hours, or other personal information of like character written or printed on such cards or passports, as supplied to dispensary patients.

5th. By destroying this advertising dodge, the value of such appointment will be decreased among a certain order, and with the number of applications for such vacancies limited, those desiring such experience for its clinical worth will be able to compete without lowering their manhood and professional dignity by the dubious methods that now obtain.

6th. When there are no advertising favors to be obtained and traded for professional work, physicians may then refuse to attend patients who can afford to pay for services. Physicians will then add dignity to themselves and their profession, destroy all questionable insinuations regarding their motives, and induce a more prosperous era for the profession at large, when they attend the deserving poor and avoid publicity.

"Let those who applaud take warning
And keep this motto in sight—
No question is ever settled
Until it is settled right."

Martin W. Curran, M.D.

FOREIGN BODIES IN THE AIR PASSAGES.

To the Editor of the Medical Record.

Sir: In the issue of the Medical Record of February 20th I notice an article on "Foreign Bodies in the Air Passages," by Dr. Fulton. In reply to his query, "Where had the foreign bodies been?" I would suggest the following: 1st. It is hardly probable that they had remained for the length of time spoken of in the œsophagus. 2d. It is less probable that they were in the trachea. The probability is that by the act of coughing they were forced into the posterior nares, where they remained until by some accident they became detached and dropped into the pharynx, whence they were expelled. Every one has noticed in cases of this kind—that is, to use the popular expression, "food going the wrong way"—that the offending substance is for the most part expelled through the nose. If it is liquid food, it causes but momentary trouble; if more solid, however, it requires a "blowing of the nose" to relieve it. In the case of a bent shingle nail it is easy to assume that its shape and size prevented it passing through, and in a child any discomfort arising from it would be overlooked.

Luke Fleming, M.D.

Tarrytown, N. Y.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 13, 1897:

	Cases.	Deaths
Tuberculosis	214	128
Typhoid fever	8	2
Scarlet fever	172	13
Cerebro-spinal meningitis	3	6
Measles	189	9
Diphtheria	199	30
Laryngeal diphtheria (croup)	19	8
Chicken-pox	22	0

Health Department and West Side German Dispensary.—The following resolutions were adopted by the medical board of the West Side German Dispensary, March 20, 1897:

"*Whereas*, On January 11, 1897, representations have been submitted to the health commissioners of New York by two officials in the health department, which are inaccurate and misleading in several important particulars and which call for an unnecessary and dangerous extension of the powers of the health department, as follows:

"1st. That the statement embodied in the first paragraph of the above report, namely, 'that it is now the universal conviction that tuberculosis is a communicable disease,' is not entirely correct and is not the opinion of many distinguished clinicians.

"2d. That, inasmuch as the patients suffering from the various manifestations of tuberculosis who are treated at their homes by their family physicians, as well as those treated at dispensaries and hospitals, are under intelligent and judicious control, the time has not come for interference with such treatment by any department of this city.

"3d. That to grant the health board officials further powers than they now possess in regard to the removal of those subjects of tuberculosis whom they may regard as dangerous sources of infection would be an interference that would be alike humiliating to the physician and intolerable to the patient and his family.

"4th. That there is no proof that more patients affected with tuberculosis need hospital care than was formerly the case; that, even if such proof were forthcoming, there is no good reason why a special hospital for consumptives should be instituted; that the department of charities is amply provided with power to enlarge their present facilities and provide medical attendants of far greater experience than the members of the health board; that the health board possesses no remedies whatsoever, either prophylactic or curative, that are not within the reach of every practitioner of medicine.

"5th. That the convictions of the health department have little weight as against the opinion of the majority of the profession in regard to the dangers of conta-

gion from tuberculosis; that the same may be said of the gratuitous and unsupported allegation that 'the interests of the patient are more easily fostered, the risks of fresh contagion diminished, and the chances of recovery enhanced in hospitals for consumptives': and that an amendment to the sanitary code, declaring that tuberculosis be officially considered a communicable disease would meet with the united and uncompromising resistance of the laity and the profession, as an arbitrary and unnecessary invasion of their rights and liberties.

"6th. 'That all institutions in this city that admit and treat cases of pulmonary tuberculosis be subjected to a regular and systemtic inspection by officials of the health board,' etc., is an uncalled-for slur on the profession, the members of which are entirely capable of providing proper hygienic safeguards without the unasked-for assistance of the board of health.

"7th. That neither the number of cases of tuberculosis reported nor the tabulated deaths from tuberculosis give any index of the prevalence of the disease; for since the health department has undertaken to exercise surveillance over it, thereby interfering with practice both public and private, and imposing unnecessary hardships upon those affected, the great majority of physicians now, in more than fifty per cent. of their cases, make no report to the board of health. In several large dispensaries, a committee of this body, appointed for that purpose, found that tuberculous cases were not reported. The apparent diminution in the death rate from tuberculosis is due to the facts that such reports tend to place a stigma upon the family, and may invalidate insurance. Therefore be it

"*Resolved*, That a vigorous protest be submitted to the board of health commissioners against this unnecessary harmful encroachment upon the domain of medical practice; and that it is recommended that in the future all far-reaching medical and sanitary measures be submitted to the Academy of Medicine and the county societies before adoption, so as to secure the necessary sanction of the medical profession: and, finally, that a copy of these resolutions be transmitted to the Academy of Medicine, the County Medical Society and Association, to his honor the mayor, and to the president of the board of health.

"THOMAS H. MANLEY, M.D.,
"LOUIS FISCHER, M.D.,
"*Committee.*"

Bacillus Smegmatis.—For the differentiation of bacillus smegmatis and the tubercle bacillus in urine, Grethe recommends staining with concentrated alcoholic solution of methlyene blue after first staining in the ordinary manner with carbol-fuchsin. The tubercle bacilli remain red, while the smegma bacilli and all other forms are stained blue.

Boric-Acid Solution.—To make a more than water-saturated solution, which will not separate when cold, triturate half an ounce of the acid with one ounce of glycerin in a mortar until a homogeneous mass is formed; then add in divided portion thirteen ounces of water at 90° F., continuing the trituration until complete solution is effected.—H. B. MASON. *Pharmacist of Clinton Prison.*

Lithia Waters.—Dr. Charles Harrington, of the Harvard school, has made public the result of his analysis of three popular lithia waters advertised as powerful solvents of vesical calculi and as cures for a number of generally considered incurable diseases. No. 1 showed no trace of lithium salts. No. 2, advertised to contain fourteen grains of lithium salts per gallon, was found absolutely free from lithia. No. 3 contained a minute trace of lithium (advertised to contain over eight grains of the carbonate). The cost is about twenty cents per quart and the medicinal properties nil. The good results come from the quantity of water consumed, mended habits, etc.—*Boston Medical and Surgical Journal.*

The Pronunciation of "Enema."—There have been several letters recently sent to the *British Medical Journal* discussing the quantity of the penultimate in the word "enema." It is hoped that the following story will throw some light on the subject: A physician was attending a distinguished scholar and cleric of this city. The patient was advised among other things to take an enema (with a long "e"). "But, doctor," said the cleric, whose classical ear had been offended, "what about the quantity— the quantity, you know?" "Oh, the quantity," said the surgeon: "well, about two pints or so."

A Crying Tic.—A fourteen-year-old daughter of John Wilson, of Augusta, Ky., is reported to have been crying all her life. Whether she plays, sleeps, or goes visiting, the cry is always the same, sounding as if it came from one in great grief. The child insists that she is unconscious of producing the sounds voluntarily.

Tetanus Traumaticus.—Injection of two-per-cent. carbolic-acid solution in dose of a Pravaz syringeful every two hours and hot baths at 40° C. prolonged for two or three hours effected cure after three weeks' treatment.—CERVELLINI, *La Sem. Méd.*, No. 51. 1896.

The Hypodermic Syringe.—I will risk the assertion that some physicians do not yet know that after use, if the syringe is placed under water with the piston withdrawn and the piston is then forced down again, a sufficient quantity of water will be pumped in above the piston to keep the instrument in working order for many days at least.— PARCELLS.

Psittacose was thought to be the diagnosis in three cases in a family in which several parrots had died soon after being purchased. Widal's test was applied to the blood and showed that the disease had been typhoid, though the course had been irregular—one patient being convalescent after the tenth day.—BLANQUINQUE, *Jour. des Prat.*, February 13th.

His Best Patients.—The late Dr. John Merriman, of Kensington, used to say that the poor were "his best patients, because he took no money from them, and God paid for them."

Ostrea Edulis is an edible dear to the American heart in whatever form it may be "served up." The *Wiener klinische Wochenschrift*, therefore, undertakes a serious task when it attempts to frighten us with a story of fatal poisoning from eating oysters, referring the cause to ptomains.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE PRESENT STATUS OF CREOSOTE IN THE TREATMENT OF PULMONARY TUBERCULOSIS, WITH AN ANALYTICAL REVIEW OF FORTY-FIVE RECENT CASES.[1]

BY JAMES K. CROOK, A.M., M.D.,

LECTURER ON CLINICAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE first real impetus to the modern use of creosote in consumption was created by the report of Bouchard and Gimbert a little less than twenty years ago.[2] The publication of so favorable an account of the drug by these distinguished authors speedily led to its widely extended use, and it has since been employed in all parts of the civilized world. It would seem that the vast amount of clinical experience which has accrued during this period would be ample to give to this substance some fixed status in practical therapeutics. Leaving aside the widely published and generally favorable reports of the earlier writers, Sommerbrodt, Von Brunn, Robinson, and numerous others, it is the author's desire in the brief scope of this paper to examine the claims of creosote in the light of the progress of the past five years. During this time an immense number of contributions pertaining to this substance, its combinations, and its derivatives have appeared in medical periodicals. Many of these, however, are of a purely chemical or physiological nature, or treat of some local or peculiar action of these preparations, and consequently have no part in our present consideration of the subject. It is our wish at this time to investigate the complex body—creosote itself—and solely with reference to its therapeutical effects in pulmonary tuberculosis. A considerable number of practical papers have recently appeared, many of them from American contributors.

Albert Albu[3] reports on the use of creosote for more than five years in the Moabit Hospital, Berlin. The drug was used in a great number of cases in the form and doses recommended by Sommerbrodt. Albu concludes that creosote possesses no specific action whatever in consumption, but he looks upon it as a useful symptomatic remedy in phthisis, perhaps the best we now have, it being valuable as an expectorant in some cases, as a stomachic in others, and as a tonic in still others. In a series of experimental investigations, Albu found that no change in the virulence of the sputum manifested itself in persons who used creosote, even in full doses.

F. P. Kinnicutt,[4] after a personal investigation of the merits of creosote, concludes as follows: that both creosote and guaiacol can be given in very large doses and with entire tolerance and without injurious effects: that such dosage apparently possesses no advantage over a much smaller one, and that it has no greater effect upon hectic and upon night sweats: that subcutaneous injections possess no advantage over administration by the mouth, and that whatever influence creosote may exert in pulmonary tuberculosis can be effected in a comparatively small dosage. Kinnicutt's researches go further to show that creosote possesses but feeble, if, any antibacillary power within the body, and that its good effects are brought about by promoting the general bodily nutrition. The drug did not cause albuminuria in any of Kinnicutt's cases, but in one patient who already had nephritis the amount of albumin was slightly increased. S. Solis-Cohen[5] believes that creosote, being a complex product, like opium or digitalis, is not entirely represented by any of its constituents. He believes that in small doses it assists digestion and prevents and checks diarrhœa. In large doses it reduces the temperature, and, as shown by the altered condition of the discharges, tends to correct the septic processes in excavations and bronchiectasis, besides serving to bring about recession in the general and local morbid phenomena. He does not attempt to elucidate the method of its action. Beverley Robinson, whose experience with creosote has probably been more extensive than that of any other American practitioner, contributes an additional article[6] on the action of the drug in phthisis. Dr. Robinson rarely gives creosote in larger doses than twenty or twenty-five drops in the twenty-four hours. As a result of his further experience he is more than ever convinced that we have in creosote a remedy of great potency in pulmonary tuberculosis. Robinson also publishes personal communications from E. L. Trudeau and W. C. Glasgow, strongly endorsing the remedy.

George H. Penrose[7] gives his experience with the remedy in the United States Soldiers' Home in Washington, D. C., where every facility is offered for the study of phthisis in its different stages. He administers creosote in the form of an emulsion with cod-liver oil and acacia, containing two minims to the drachm. In some cases he has increased the drug to forty, fifty, and even sixty minims daily. He states that while no cases were cured absolutely, many of them were improved to a marked degree. H. S. Stark[8] believes that creosote owes its virtues to its antifermentative influence in the alimentary canal. It thus favors nutrition and assimilation by increasing the appetite, promoting absorption, and enhancing digestion. By virtue of this action the body weight increases, while the subjective symptoms, cough, expectoration, and the hectic phenomena gradually disappear. Stark also uses the remedy as a prophylactic in conditions in which consumption seems to be threatened. He rarely uses it in larger doses than twenty minims in twenty-four hours, an average dose being four minims three times a day. He concludes that creosote is no longer to be regarded as a temporary innovation or a fad, but a

drug that has come to stay as an antituberculous remedy.

J. T. Whittaker,[1] in the course of a thoughtful review of this subject, states that as creosote does not control the fever of tuberculosis, even when given to saturation, it is no radical or direct cure for tuberculosis. But if it can cure indirectly, or if it will only arrest the disease, or relieve complications, it will hold its place until something radical is found. He admits that the drug exerts no apparent destructive influence on the bacillus tuberculosis in the body, but pertinently asks whether it may not be poisonous to the associated micro-organisms, many varieties of which, as we know, exist in tuberculous sputum. Whittaker offers no satisfactory answer to these questions, but concludes: (1) that creosote is harmless in its administration; (2) that it has no direct influence on the bacillus; and (3) that its virtue, which is undeniable in most cases, is exerted chiefly but not entirely upon nutrition. Fürbringer[2] states that he has not given creosote for the last one or two years on account of want of success with it. In half the cases no influence was observed from its administration, and in one-fourth it appeared to act injuriously; the remedy hurt the stomach and the patients lost appetite and became miserable. J. Burney Yeo[3] records himself as being highly in favor of creosote and guaiacol in the treatment of phthisis pulmonalis. F. M. Warner[4] notes the following marks of improvement under the creosote *régime* in phthisis: "The general condition rapidly improves. In some cases the appetite increases, the cough becomes less during the daytime, and after a while also at night. Hæmoptysis ceases. If the sputum has been tinged with blood, this condition disappears. The weight of the patient always increases at first, then it is apt to remain stationary. In exceptional cases it may lessen and then a gradual increase takes place." Illustrative cases are presented to substantiate these statements. Warner is in favor of saturating the system as speedily as possible. Although the daily dosage reached over one hundred minims in some cases, in none were any bad effects from creosote observed. There was no change whatever noted in the urine from either large or small doses. A few patients with an idiosyncrasy might get up a transient nausea, with vomiting and diarrhœa or headache and vertigo. Warner's opinion of creosote is altogether favorable. Delafield[5] states that creosote exerts a real effect on the bronchitis (of tuberculosis), but unfortunately it is apt to disorder the stomach. He therefore prefers to use it by inhalation or enema. A. J. Garland,[6] of New Zealand, in a brief communication reports excellent results from the use of creosote, especially when aided by the advantages of a high elevation. H. C. Wood[7] states that, while creosote is a valuable remedy in phthisis, in his own experience it is not a specific, and will rarely or never bring about a cure.

R. W. Wilcox[8] is an advocate of creosote in preference to its derivative, guaiacol. He does not find the latter substance so useful as creosote when given in doses equivalent to its percentage of creosote or even in equal doses drop for drop. Wilcox has abandoned capsules on account of their nauseousness and recommends the enteric pill of a well-known manufacturing house. He endorses the carbonate of creosote on account of its easy administration and assimilation. At the meeting of the American Climatological Association for 1894[9] the subject of the creosote treatment of tuberculosis was brought up for discussion. The use of the drug was endorsed by most of the speakers. Dr. A. L. Loomis, of New York, being the only opponent to its employment. M. Burlureaux[2] concludes that creosote is a more important diagnostic agent than tuberculin. He has found that when patients cannot tolerate the drug, even in very small doses, they are usually beyond hope, but when they can support large doses their chances are good for complete cure. Intolerance for creosote, he claims, is the test of depreciation of the organism and deterioration of the vital powers. J. R. Conway[3] looks upon creosote as possessing a positive curative influence. He states that in his experience of upward of four hundred cases he has not been disappointed with the effects of the drug in one. He administers it in the form of capsules combined with cod-liver oil, and pushes it to the point of saturation. He states that the treatment should continue for at least two years, no matter how well the patient may appear to be. J. Wessinger[4] uses creosote with gratifying success. He recommends it especially in the form of the carbonate and of oleocreosote. J. V. Shoemaker says:[5] "In the treatment of tuberculosis creosote is perhaps the most valuable remedy that we possess." W. H. Dukeman[6] is an advocate of creosote in the treatment of pulmonary tuberculosis, and gives his preference to the carbonate. Joseph Lafage[7] is highly pleased with the action of creosote in pulmonary affections. He looks upon the substance as possessing an elective action upon the lungs, directly combating their diseases and especially the causes thereof. It should, therefore, in his opinion be regarded as a specific medicament. In a more recent contribution[8] Burlureaux reaffirms his faith in creosote and reiterates his opinion as to its prognostic value. He believes, however, that the best results are obtained by the subcutaneous use of the drug. For this purpose the ordinary creosote of commerce is redistilled at 207° C. (404.6° F.). It is then mixed with from fourteen to twenty parts of sterilized olive oil and injected, subcutaneously if the dose is large, into a muscle if only a small dose is required. Burlureaux administers to children from one to five years of age one to seven minims of creosote daily, to an adult from fifteen minims to a drachm daily. He has in some instances given as much as four drachms in the twenty-four hours in this way. He has thus treated two hundred and sixty-two patients, over two hundred of whom were much improved in health.

The author believes the foregoing extracts fairly cover the field marked out for this paper. It will be seen that the clinical evidence of the past five years is almost invariably unanimous in favor of creosote as a remedy in pulmonary tuberculosis. The reputation of the drug is therefore not on the wane, and it is apparently more strongly intrenched as an antiphthisical remedy than at any previous period.

The writer's personal experience with creosote has extended over the past seven years. During this time he has treated many hundred cases with the drug at the clinic of the out-patient department of Bellevue Hospital and the general medical clinic of the Post-Graduate School, as well as a considerable number in private practice. On April 20, 1895, he presented a paper on the subject[9] to the New York Post-Graduate

[9] "Observations on Creosote and its Derivatives," the Post-Graduate, New York, September, 1895.

Clinical Society, in which the ground was taken that creosote exerted very little influence over the course of pulmonary phthisis, but that it possessed a certain beneficial effect as a stomachic tonic, and in some cases as a pulmonary disinfectant. It must be admitted, however, that prior to that time it was the author's custom to administer the drug in small quantities, six to ten minims daily being an average dose, while the maximum rarely extended to twenty minims.

Since the reading of this paper the author has pushed his inquiries in this direction and has used creosote in as large doses as it seemed safe to administer. During this period forty-cases of pulmonary tuberculosis have been treated with the drug and kept under observation for a period ranging from three weeks to twenty-seven months. The results of treatment were carefully noted, and the chief facts relating to the cases will be found in the subjoined table.[1]

No.	Name.	Age.	Sex.	Stage of Disease when Creosote Begun.	Time Under Treatment.	Time Under Creosote.	Maximum Daily Dose of Creosote.	Results of Treatment.	Remarks.
1	J. M.	49	F.	First	1 year.	8 months.	36 ♏	No benefit observed; patient now failing.	Patient's condition was much deteriorated while under creosote, by loss of son.
2	L. G.	21	F.	Second	2½ years.	2 years.	64 ♏	Apparent cure; disappearance of symptoms and signs.	Patient at this time weighs 2 pounds more than ever; has slight clearing of throat but no cough.
3	M. D.	28	F.	Third. cavity ..	6 weeks.	6 weeks.	18 ♏	Slight improvement in cough at first; afterward exacerbation of symptoms.	
4	J. J.	40	M.	First.	1 year.	10 months.	40 ♏	No apparent change in any way.	
5	F. K.	18	F.	Beginning of second.	4 months.	5 weeks.	12 ♏	Cough somewhat diminished; expectoration improved in character.	Patient disappeared from observation while under creosote.
6	M. L.	28	F.	First.	2 months.	1 month.	12 ♏	Disappearance of cough and all symptoms of phthisis.	
7	J. D.	36	M.	Third. large cavity.	18 months.	5 months.	40 ♏	No improvement; patient moribund when last seen.	
8	C. A.	43	M.	Hemorrhagic phthisis 3 years; second.	1 year.	1 year.	44 ♏	Patient has intervals of improvement and deterioration. On the whole a little better than when treatment began.	Creosote exerts no influence whatever on hemorrhages; had 7 separate attacks in 1 day while taking 36 ♏.
9	M. J. P.	40	M.	Second	11 months.	10 months.	48 ♏	Disappearance of signs and most of symptoms.	Patient has regained normal weight and strength; slight dulness at right apex; a little cough without expectoration.
10	P. H.	42	M.	First.....	11 months.	11 months	36 ♏	Disappearance of symptoms and signs.....	Patient in good health and able to attend to his duties, but weighs 15 pounds less than formerly.
11	M. R.	33	F.	First	1 month.	3 weeks.	12½ ♏	No appreciable change.	
12	Y. L.	59	M.	First.....	1 month.	3 weeks.	18 ♏	No visible effects from creosote.	
13	J. K.	35	M.	Second	2½ years.	5 months.	40 ♏	No apparent benefit; patient failing.	
14	J. B.	21	M.	First	3 weeks.	2 weeks.	12 ♏	Negative results.	
15	J. G.	50	M.	Second	10 months.	7 months.	48 ♏	Disease advanced to third stage; no benefit from creosote; patient now confined to room in dying condition.	Patient had exceedingly irritable stomach, which condition was not prejudiced by creosote.
16	L. C.	25	F.	Second	5 weeks.	4 weeks.	15 ♏	Negative results.	
17	W. H. L.	35	M.	First	10 months.	2 months.	24 ♏	Apparent cure; total disappearance of all symptoms and signs.	
18	H. D.	33	F.	Second	2 months.	2 months.	28 ♏	Gain of 7 pounds in weight, also improvement in other symptoms.	Patieot was still improving when last seen; was a victim of flatulent dyspepsia, which creosote seemed to improve.
19	S. K.	32	M.	Second	7 weeks.	7 weeks.	20 ♏	No apparent change.	
20	B. C.	23	F.	Hemorrhagic phthisis; second.	6 weeks.	6 weeks.	18 ♏	Improvement in cough but hemorrhages continued.	
21	M. O.	36	M.	Second	5 weeks.	3 weeks.	18 ♏	No visible results.	
22	K. P.	22	F.	Second	2 months.	2 months.	28 ♏	Patient gained 9 pounds in weight but lost 2 ponnds afterward; general result good.	Night sweats increased but all other symptoms ameliorated; some gastric irritability but creosote well borne.
23	A. G.	32	F.	First	2 months.	7 weeks.	24 ♏	Slight improvement in general condition; no material chaoge.	
24	M. F.	35	F.	Second	4 weeks.	4 weeks.	18 ♏	No changes noted in disease.	
25	J. G.	40	M.	Third, cavity ..	3 weeks.	3 weeks.	12 ♏	Negative results.	
26	L. B.	20	F.	Second	5 weeks.	2 weeks.	12 ♏	Creosote caused cramps and indigestion and was discontinued.	Had to resort to sedative remedies to overcome gastric and intestinal irritability.
27	J. R.	35	M.	Second	4 years.	7 weeks.	12 ♏	Patient not visibly improved by creosote; died June, 1896.	Odor of drug excited extreme aversion on part of patient; could not be persuaded to continue it.
28	M. R.	17	F.	Second, phthisis; Florida.	9 weeks.	5 weeks.	15 ♏	Disease pursued a steady downward course; patient died after 9 weeks of treatment.	
29	J. F.	60	M.	Second	3 months.	3 months.	36 ♏	Excellent; disappearance of symptoms and physical signs and return of weight to normal.	Patient still has an occasinnal coughing effort without expectoration.
30	L. C.	27	M.	First	8 months.	3 months.	16 ♏	Some improvement; a little better at end of 3 months' creosote treatment than at beginning.	Creosote disagreed at beginning of hot weather and had to be discontinued.
31	J. C.	38	M.	Second	3 months.	7 weeks.	25 ♏	No improvement; disease rapidly passed to stage of excavation.	Patient was in extremis when last seen.
32	A. B.	22	M.	Second	7 months.	5 months.	33 ♏	Very good at first; patient gained 11 pounds in weight in 3 months, then began to fail rapidly.	Disease passed into third stage and patient died in June, 1896.
33	L. Y.	32	M.	First	4 months.	4 months.	27 ♏	Patient did badly at first; creosote disagreed; then commenced to improve slowly.	Patient is now taking 27 ♏ of creosote daily with apparent good results.
34	A. S.	26	F.	First	8 months.	3 months.	24 ♏	No improvement under creosote and it was discontinued.	
35	M. K.	23	F.	Second	4 years.	5 months.	16 ♏	Creosote did not check disease, although it progressed very slowly while under its use.	Patient now has large cavity in right lung and is near the end.
36	J. O'D.	34	M.	Third.....	3 months.	3 weeks.	12 ♏	Disease progressed rapidly; patient died August, 1896.	
37	L. O'D.	26	F.	First	6 months.	4 weeks.	12 ♏	No change was observed while taking creosote.	
38	L. B.	36	F.	Second	4 months.	8 weeks.	20 ♏	Now under treatment; disease progressing slowly in the wrong direction.	
39	B. M.	19	M.	First	3 months.	5 weeks.	20 ♏	Patient, now under treatment, is showing some improvement.	
40	T. B.	38	M.	Laryngeal phthisis 1 year; pulmonary 5 months.	2 months.	4 weeks.	12 ♏	Patient has shown a little improvement.	
41	E. W.	35	M.	Third, cavity..	10 weeks.	5 weeks.	24 ♏	Intervals of improvement.	
42	W. A.	25	F.	Second	3 months	.....	12 ♏	No appreciable change can be noted.	
43	R. D.	22	F.	First	10 weeks.	.....	12 ♏	Excellent; patient gaining weight and strength and symptoms disappearing.	
44	C. P.	28	M.	Beginning of second.	5 weeks.	5 weeks.	20 ♏	A little improvement.	
45	W. O'B.	29	M.	Third. cavity ..	2 months.	5 weeks.	16 ♏	Patient sank steadily and died within two months.	Patient's condition exceedingly bad at beginning of treatment.

[1] Reference was made to some of these cases in a paper presented to the New York State Medical Society, January, 1894. MEDICAL RECORD, 1894.

It should be stated that the term "stage" in the table refers to the condition of the disease as represented by the physical signs. The first stage embraces those cases showing the signs of incipient pulmonary catarrh; the second includes those in which more or less consolidation had occurred, while the third stage indicates the cases in which excavation or the formation of cavities was present. All the cases presented the customary histories and subjective symptoms of consumption. Analyzing these cases with reference to the effects produced by creosote, we obtain the following results: Five cases were apparently cured, *i.e.*, there was a complete disappearance of all the symptoms and physical signs of phthisis. Five cases showed marked signs of improvement; eight received some degree of benefit. In thirteen cases no changes whatever were observed in the progress of the disease. Eight subjects died or were moribund when last seen, while the remainder passed from observation before any definite idea of the action of creosote could be formed. None of this latter class was improved up to the time of the disappearance of the patient. Speaking broadly then, we may say that of the forty-five cases under observation, eighteen, or forty per cent. of the number, were improved, while twenty-seven, or sixty per cent., received no benefit. Concerning the five patients apparently cured, the following facts from the table are of interest:

Case I. (No. 2 in table).—Female, aged twenty-one years; was in the second stage of phthisis when first seen. Under observation two years and three months, under creosote two years; reached a maximum dose of sixty-four minims of creosote daily. Average dose, thirty-six minims daily. This patient is still under observation and is apparently in excellent health. She is now taking twenty-four minims of creosote daily as a precautionary measure.

Case II. (No. 6 in table).—Female, aged twenty-eight years; in the first stage when coming under treatment. Kept under observation two months, the last month being under an average daily dose of twelve minims of creosote. There was a quick disappearance of the symptoms and physical signs, and when last seen the patient expressed herself as being as well as ever.

Case III. (No. 10 in table).—Male, aged forty-three years; in the first stage when coming under observation. Under treatment eleven months, all the time under creosote, reaching a maximum of thirty-six minims daily, which was maintained during most of this period. All symptoms and signs disappeared after four months of treatment. Patient is still seen occasionally. He is at work and in good health.

Case IV. (No. 17 in table).—Male, aged thirty-five years, in the first stage when applying for treatment. Under observation ten months, under creosote two months. Maximum dose of creosote twenty-four minims daily. This patient made a good recovery and remained perfectly well for a period of six months. A few days since (October 19, 1896), he applied for treatment for a "cold," which he claimed to have contracted as a result of exposure shortly before. He evidently had a mild attack of bronchitis of the larger tubes, with no indication of a return of the phthisical manifestations.

Case V. (No. 29 in table).—Male, aged sixty years. Had well-marked consolidation when coming under treatment. Under creosote three months; speedily reached the maximum dose of thirty-six minims, which was continued for six weeks. This patient was in a bad condition when first seen. He was suffering from frequent hemorrhages, night sweats, and loss of appetite, and had already lost twenty-four pounds in weight. His improvement was marked and rapid. In three months he regained every pound of his lost weight: the cough, hemorrhages, and night sweats ceased, and the physical signs were reduced to a slight hardening of the percussion quality and some diminution of the breathing sounds over the affected area. The patient was deemed to be entirely well.

It should be stated that some of these cases received cod-liver oil, hypophosphites, iron, etc., from time to time while under treatment, yet creosote was the main reliance and to it were attributed the good results.

Of the five cases receiving marked benefit, two were in the first stage and three in the second stage at the time of the first application for treatment. These cases made excellent progress, and it is believed that at least two of them may eventually be added to the list of cured. Of the eight cases showing a slight but appreciable improvement, we find that four were in the second stage, three in the first, and one in the third stage when first seen. Of the eight who died or were in a dying condition when last seen, four were in the second and four in the third stage of phthisis when coming under treatment. These facts would seem to indicate that the best results from creosote as well as from other forms of treatment may be expected when the treatment is begun early in the disease and that little can be accomplished after the later stages are reached. It was found that the remedy was exceedingly well tolerated even when the larger doses of forty to sixty minims daily were given. No renal symptoms were developed in any case. Yet it was the author's experience that it was seldom necessary to carry the average daily dosage beyond thirty or thirty-five minims, the best results being apparent in most instances when the smaller of these doses was given.

There are numerous methods of administering creosote and the author has no new formula to add to the already very large list. On this question each case must be a law unto itself. In many instances it will be found advisable, or even necessary to vary the method of exhibition. For example, some persons take it exceedingly well combined with cod-liver oil in the form of capsules. If these become nauseous or repulsive, pills may be tried. There are several excellent pills on the market which, according to the author's personal investigation, are easily taken, easily digested, and easily assimilated. As many as fifteen pills daily have been given with gratifying results, each pill representing from one to four minims of creosote. Some patients take without difficulty as much as five or six drops at a dose by merely agitating it in a two or three ounce bottle with a drachm or two of whiskey and an ounce or two of water. Then there are numerous mixtures of creosote with alcohol, gentian, cinchona, rectified spirits, sherry wine, etc.

The clinical results obtained by the author with creosote cannot be classed as brilliant. They do not compare with Sommerbrodt's record of twenty-seven per cent. of recoveries in five thousand cases,[1] nor with Conway's,[2] of over four hundred cases without a disappointment. But they corroborate the general verdict that a certain proportion of phthisical cases is susceptible of arrest and cure, even after a considerable degree of progress has been made by the disease. Any drug that can be shown positively and unmistakably to possess this power, even in a single case of this fatal malady, is deserving of the most reverential consideration by the profession. The author has no hesitation in stating that with an experience of several thousand cases of phthisis, in which perhaps every remedy supposed to be useful in this affection has been tried, he has found none which exerted the influence shown by creosote. Nor does the writer believe that any other remedy or combination of remedies will

[1] Centralb. f. Therap., x., 225. Also, Therapeut. Monatsh., iii.
[2] Loc. cit.

produce a favorable influence and appreciable improvement in forty per cent. of cases.

The foregoing review of the literature of creosote, together with his personal experience with the remedy, leads the author to formulate the following conclusions:

1st. Although the human race continues to sicken and die of pulmonary tuberculosis, it is the consentaneous voice of the medical profession, as shown by reports gathered from all parts of the world, that we have in creosote a remedy capable of arresting a certain percentage of cases.

2d. This drug should therefore be administered carefully, systematically, and continuously in every case of consumption, provided it is well tolerated and there is no contraindication or idiosyncrasy as to its action.

STAB WOUND OF THE HEART AND PERICARDIUM—SUTURE OF THE PERICARDIUM—RECOVERY—PATIENT ALIVE THREE YEARS AFTERWARD.

By DANIEL H. WILLIAMS, M.D.,

SURGEON, FREEDMEN'S HOSPITAL, WASHINGTON, D. C.

The following case is deemed of sufficient importance to be reported three and a half years after its occurrence. The writer's illness about the time of the patient's recovery and a change of duties to his present position have prevented previous publication.

James Cornish, an expressman, aged twenty-four years, during an altercation received a stab wound through the fifth costal cartilage, injuring the internal mammary vessels and wounding the pericardium and heart. The kind of knife and length of blade could not be determined from the patient.

He was admitted to Provident Hospital, Chicago, July 9, 1893, at 7:30 P.M., with a stab wound about one inch long, three-fourths of an inch to the left of the sternum, through and in the long axis of the fifth cartilage. A probe recognized only a superficial wound, but during the night there were such persistent

hemorrhage, pain over the cardiac area, short, sharp, shrill cough, and such pronounced symptoms of shock that a re-examination the following morning showed that the knife had penetrated the fifth costal cartilage in its long axis, at least far enough to wound the internal mammary artery and veins. When the knife had been withdrawn the elastic cartilage closed behind it, pre-

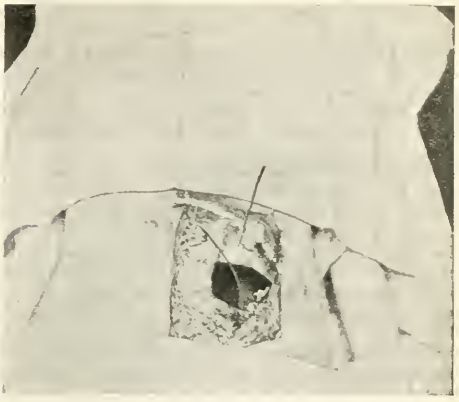

Fig. 2.—Experiment on Cadaver, Showing Ligation of Internal Mammary Vessels.

venting the introduction of the probe the night previous. It was found later on that it was impossible to introduce a piece of cardboard or paper into or through this slit made by the knife.

The accompanying sketch shows the method pursued in ligating the internal mammary vessels as well as the dissection made in approaching the pericardium. In some examinations made afterward to study the relations of the pleura to the sternum and cartilages, it was found that a knife blade introduced through the fifth costal cartilage three-fourths of an inch to the left of the sternum would sever the internal mammary artery and pierce both layers of the pleura; the opening on withdrawing the knife would, however, reclose, valve-like, preventing the entrance of air into the thoracic cavity. The lung would remain in contact with the thorax. On resecting the cartilages and permitting air to enter, the lung collapsed somewhat and receded some distance from the anterior chest wall. The heart also gravitated backward, so that the distance of the pericardium from the anterior chest wall was greater than before the air had entered the cavity. To reach the pericardium, therefore, during life by an incision large enough to enable one to operate, would unavoidably permit the entrance of air, and the depth of the pericardium and heart from the surface by reason of this opening would increase the difficulties of operation. These difficulties were encountered in dealing with this case. It was shown during these investigations that it was impossible to reach the pericardium without piercing both layers of the pleura. This left pleural cavity slowly filled with bloody serum, which was not infected with pus organisms. This was proven by the removal of eighty ounces of bloody serum three weeks afterward without any serious disturbance, local or constitutional. To this absence of infection is probably attributed the successful progress and termination of the case.

Operation.—On the morning following admission there were present Drs. George H. Hall, Howard C. Chislett, E. E. Barr, William E. Morgan, and William Fullar. The original wound was lengthened to the right as far as the middle of the sternum. A second incision was made from the centre of the first and carried over the middle of the cartilage and fifth rib, about six inches in length. The sternum, cartilage,

and about one inch of the fifth rib were exposed. The cartilage of the fifth rib was separated at its junction with the sternum and at a point two and one-half inches from the sternum and one-fourth of an inch from its attachment to the rib. The inferior attachments of the incised piece were separated, leaving the superior ones in place. The incised piece was reflected upward, making an opening about two inches long and one and one-half inches wide, bringing the internal mammary vessels into view. These vessels were ligated above and below with small catgut. This large opening permitted easy ligation and manipulation. To secure additional room an incision was made in the fifth intercostal space. The heart and lung being depressed backward, a small punctured wound of the heart, about one-tenth of an inch in length and about one-half of an inch to the right of the right coronary artery, between two of its lateral branches, was seen. The wound in the pericardium was about one and a quarter inches in length. There was no hemorrhage from the heart or pericardium. The edges of the pericardium were held by long smooth forceps, and a continuous suture of fine catgut was made. Before the pericardial wound was closed it was irrigated with normal salt solution. The temperature was 100° F. Catgut was used in closing the intercostal and subcartilaginous wounds and silkworm gut in the cartilages and skin. A few silkworm-gut sutures were left long in the external wound, so as to permit easy removal, in case it should be necessary, on account of infection or hemorrhage. A dry dressing was applied.

As proven by the result there was no cardiac, pericardiac, pleural, or wound infection. The accumulation of bloody serum in the pleural space was the natural result of an extensive operation, gravity drainage in the direction of the least resistance. It seemed a wise provision that the fluid did drain into this space where it could do the least harm and where was the easiest place to get at it and remove it. Draining into this space kept the wound dry, a most favorable condition for primary healing.[1]

History following operation. First twenty-four hours: Highest temperature, 103° F.; pulse, 130, thin and weak; some pain in the region of the wound; slept six hours without anodynes.

Second twenty-four hours: Highest temperature, 102° F.; pulse, 134, weak and thready; slept four hours; paroxysms of coughing followed by hiccough lasting three hours; some pain in the region of the diaphragm.

Third twenty-four hours: Highest temperature, 103° F.; pulse, 118; slept eight hours; vomited at intervals; some pain in the wound.

On the evening of the fourth day the temperature was 99° F.; pulse, 96. From this time until the fifteenth day the temperature was below 100° F.; no notable symptoms were manifested. Daily observations were made of the heart and pericardium.

On the seventh day he complained somewhat of pain in the right thorax; result of examination of this side negative. On the left side flatness extended up to the third intercostal space in the axillary line. Vocal sounds, respiratory sounds, and vocal fremitus were absent. The lower intercostal spaces bulged; the left side measured one and one-fourth inches more than the right side; the cardiac area was increased; the heart sounds were muffled and distant. Diagnosis of probable pericarditis with effusion (purulent) was ventured. Positive diagnosis of effusion into the left pleural cavity was made on this date. The question arose as to whether there was an accumulation of fluid in the pericardium, but this could not be proven until the fluid in the pleural cavity was removed.

The patient continued to improve until July 27th, when Dr. Stanley P. Black, attending physician to Provident Hospital, saw him and left the following statement on the chart:

"July 28, 1893.—Dulness over the left side, anteriorly and laterally, as high as the third intercostal space. Cardiac area enlarged over lower portion.

"Auscultation: Heart tone muffled; no friction sounds; lungs, left and right, high pitched; prolonged expiration, more marked on the left side. Inferiorly at left side at extreme edge of lung a few fine crepitant râles on deep inspiration; posteriorly, lower edge of lung, friction sound.

"Conclusion: Pericarditis with effusion. Pleuritis sinister minimal."

Operation was done, August 2, 1893, for the removal of fluid from the pleural space, by incision in seventh intercostal space two inches long, parallel to the ribs. Eighty ounces of bloody serum were removed. Infection of the pleural cavity was prevented by allowing the fluid to flow under several thicknesses of wet sterile gauze. The gauze was kept wet by a stream of water playing on it. If the pressure from within is greater than the atmospheric pressure, this is all that is ever necessary to prevent the invasion of infection in emptying a cavity. Adhesive straps were applied to this side of the chest from the armpit to the eleventh rib. Following this operation there was nothing worthy of note. The patient left the hospital well, August 30th.

The writer saw him at work in the Union Stock Yards, Chicago, two years afterward. Dr. E. E. Barr saw him in December, 1896, more than three years afterward, and reports him well.

"Experiments have been made on the lower animals to determine the feasibility and usefulness of sutures of the heart and pericardium. Philippov[1] experimented on dogs and rabbits with various results. Del Vecchio[2] experimented on dogs and concluded that suture of heart and pericardium was practicable in the human subject."

"Ferrarresi[3] reports the case of a woman who was stabbed, the left internal mammary artery being severed at the level of the fourth cartilage. He resected from the third to the fifth cartilages to reach the internal injury, and, as in his opinion the woman's condition did not warrant suturing the heart, he sterilized tampons, lightly compressing the heart and stopping the bleeding. She recovered. He seems to prefer the tampon to the suture."

"As showing the curability of heart wounds, Turner[4] reports the case of a young man who received a horizontal incised wound over the left fifth cartilage, the cartilages being slit one and three-fourths inches; the red blood spurted and air hissed out in each heart-beat or respiration; the pleura rapidly filled with blood."

The man lived four and one-half months, the first discharge of blood changing to sero-sanguineous fluid and then to purulent; the left pleura became a pus cavity. This cavity was opened and discharged by resecting the fifth rib posteriorly. The man at once improved but eventually died, as stated, and of "extracerebral apoplexy." The necropsy showed the left lung collapsed, pleura adherent to pericardium; the pericardial and cardiac wounds were cicatrized; the wound in the heart was three-fourths of an inch long, horizontal, and penetrated into the intraventricular septum five-eighths of an inch; the left coronary artery had been divided.

[1] The white squares seen at either end of the wound mark the limit of the incision.

Dr. Elkton, in an instructive article in a German medico-legal journal, emphasizes the fact that with all the modern methods of examination it is extremely difficult to diagnose wounds of the pericardium and heart. "There are no pathognomonic symptoms; the diagnosis must be arrived at from analysis of all the symptoms." [1]

Moullin, page 862, under wounds of the heart, mentions that on "one occasion I attempted to close the wound in the pericardium with suture," and ends without saying why he did not proceed further.

In the great number of wounds of the heart and pericardium the aseptic tampon has been the means of controlling hemorrhage and preventing infection, in all successful cases.

The Index Catalogue and Medicus of the National Medical Library, surgeon-general's office, Washington, D.C., do not give a single title descriptive of suture of the pericardium or heart in the human subject. This being the fact, this case is the first successful or unsuccessful case of suture of the pericardium that has ever been recorded.

By the courtesy of Dr. D. S. Lamb, pathologist of the Army Medical Museum, I was enabled to examine all of the specimens of pericardial and heart wounds in the museum. In none was there any history of operation.

THE TREATMENT OF TRIGEMINAL NEURALGIA.[2]

By WILLIAM M. LESZYNSKY, M.D.,

CONSULTING NEUROLOGIST TO THE MANHATTAN EYE AND EAR HOSPITAL, LECTURER ON MENTAL AND NERVOUS DISEASES AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL, ETC.

WHILE deliberating upon the selection of a suitable topic which might be of interest to the general practitioner, I was consulted by a young woman who had been a sufferer from trigeminal neuralgia for a number of years, and had obtained very little or no benefit from the medical treatment she had received.

The observation of this case (which will be referred to later) hastened my decision. I shall therefore ask your attention to "The Treatment of Trigeminal Neuralgia," which I trust will prove of sufficient interest to merit your careful consideration. At the outset I should like to have it clearly understood that, as this paper is based upon the results of personal clinical experience, I shall endeavor in the limited time allotted to me to confine my remarks almost exclusively to the methods that have proved most serviceable and satisfactory in my hands. Much that I might say to you must be left unsaid, as this is neither the time nor place to indulge in a lengthy dissertation or a tedious narration of the views of others.

Trigeminal neuralgia is of comparatively frequent occurrence in the routine work of the general practitioner. It also comes within the scope of the ophthalmologist, laryngologist, and dental surgeon. The neurologist generally sees these patients after the disease has existed for a long time, and occasionally when complications are present.

The term "neuralgia," which means simply "nerve pain," should be restricted to the cases in which the malady consists only in functional disturbance. While the usual type of this affection may be looked upon as idiopathic in the vast majority of instances, the more severe form, known as tic douloureux or epileptiform neuralgia (which generally occurs after forty years of age, and in old people), may be considered as degenerative. In order to avoid repetition, I shall discuss them as one condition, although the latter is probably dependent upon changes in the nerve itself. It is obviously unnecessary to enter into a detailed description of the symptomatology, with which you are all more or less familiar, or may read at leisure.

Of all the peripheral nerves, the trigeminus or its branches is most frequently the seat of neuralgia. We are thus reminded that it is the largest cranial nerve, that it is a nerve of special sense, of common sensation and motion, and that it is the great sensory nerve of the head and the motor nerve of the muscles of mastication.

The diagnosis of trigeminal neuralgia rests mainly upon the following points (Erb):

1. That the pain is limited to a definite nerve path, either trunk, branch, or area of distribution, and that it is usually confined to one side.

2. That the pain is, without any obvious reason, either intermitting or at least distinctly remitting in character.

3. That the pain presents very peculiar characters, and is extraordinarily acute.

4. That there are certain spots in the course of the nerve or in the area of its distribution which are very sensitive to pressure.

5. That the pain is associated with sensorimotor, and vasomotor, and secretory phenomena.

6. That the pain is unaccompanied by any inflammatory or local symptom.

Each division of the nerve or its branches may be independently affected, or all branches may be involved simultaneously.

Certain diseases seem at times to possess a predilection for certain branches. Thus, the supraorbital nerve is affected more frequently after infections such as grippe or malaria; the superior maxillary nerve from defective teeth, particularly the molars. In neuralgia of the auriculo-temporal branches, the pain is sometimes limited to a narrow stripe extending over the vertex from ear to ear, and is often occasioned by syphilis. An irritative process in the pons, involving the sensory root of the nerve, may be the cause of severe trigeminal pain. The diagnosis of such a lesion can be made only in the presence of associated symptoms of cerebral disease.

Neuralgia of a persistent character, affecting particularly the first branch, may be due to errors of refraction or other ocular defects, intra-nasal disease, or disease in the frontal sinus, or it may result from exposure to cold.

In this connection I must briefly mention a very important clinical fact not referred to in text-books. It is that the severe pain over the eye and forehead, occurring in acute inflammatory glaucoma has at times been mistaken for neuralgia, the patient treated accordingly, and the error discovered too late to save the eye from irreparable damage.

It will thus be seen that when investigating the cause of the neuralgia, our chief aim should be to ascertain as far as possible whether it arises from an affection of the nerve alone, or from an abnormal condition of the tissues or organs in immediate relation with the nerve in any part of its course, or from a morbid state of the blood and secretions generally.

The latter element is of paramount importance, and in many cases (in addition to a neuropathic heredity, which is often a predisposing factor) is the underlying constitutional cause.

It may be an autotoxæmia, resulting from constipation or other disturbances in the gastro-intestinal tract, a gouty or rheumatic diathesis, a previous syphilitic infection, or existent diabetes, or chronic renal disease, etc. Syphilis may also set up a gummatous periostitis in the narrow canals, making pressure on the nerve as well as interfering with its circulation. Overwork,

[1] Int. Journal of Surgery, August, 1893.

[2] Read before the Harlem Medical Association, February 3, 1897, and the Practitioners' Club of Newark, N. J., March 1, 1897.

constant mental strain, anxiety and worry, sexual or other excesses, or anything else which reduces the vitality and nutrition are more or less potent in the causation of this painful affection.

The future welfare of the patient and the early control of the disease rests mainly with the general practitioner, who sees these cases in the earliest period of their development. A patient thus complaining of facial pain should be carefully examined, and the source of the trouble eliminated as soon as practicable. This is possible in almost every case. It behooves you as medical practitioners to be very thorough in your examination, especially of patients in the middle period of life. Even when the pain is slight, it should not be neglected and looked upon as trivial. The paroxysms of pain involving the lower branches of the nerve are at times accompanied by tonic spasm of the facial muscles, and quite regularly by vasomotor and secretory disturbances. Such a painful condition, if it persists, interferes with the various functions of the body, and nutrition becomes materially reduced, partly on account of the pain excited by mastication, and partly by the prevention of sleep. It also occasionally leads to mental disturbance, such as depression or even melancholia. Only those who have witnessed the excruciating and uncontrollable agony manifested during a paroxysm of tic douloureux, when the disease is fully developed, will appreciate the gravity of the affection. It is not at all surprising that such patients have sometimes been driven to suicide.

At first our attention should be directed to the mitigation of the pain, this being the urgent and obtrusive symptom. The cause must then be sought and removed if feasible, and the physical and mental condition studied, with a view toward improving the general health.

When we consider that the neuralgia is generally the result of constitutional causes, which have disturbed the stability of the nuclei or nerve centres, or interfered with the nutrition of the nerve, we can readily comprehend the futility of basing our entire management of the case upon symptomatic treatment of the pain alone. And yet this is of common occurrence.

I have observed the inflexible rule, never to institute systematic treatment until the teeth are pronounced in good condition by a competent dentist. Apparently healthy teeth may have exostoses or other disease at the roots, and thus be the cause of the pain. The practice, or rather malpractice, of extracting healthy teeth is only mentioned to be condemned. Experience has taught me that very few of these patients who consult the neurologist have escaped this unwarranted mutilation. The stereotyped statement familiar to our ears is: "I have had a number of (or all) teeth extracted, but the pain continues just the same." On the other hand, old and middle-aged people who have had diseased teeth extracted, are sometimes attacked by a very severe neuralgia of the toothless alveolar processes. It has been assumed that this is caused by pressure on the torn nerve filaments by the newly formed bony tissue.

One of the most essential therapeutic measures is rest of the muscles of mastication and articulation, and quite often complete bodily rest in bed. This can usually be accomplished by forbidding conversation and the use of solid food. The latter may be replaced by fluid or semifluid food, such as milk, eggs, meat juice, beef pulp, etc. Rest and nourishment are equally as important in neuralgia as in other affections of the nervous system. In the beginning of treatment it has been my custom to instruct the patient to have the food either poured into the mouth and swallowed while recumbent, or to draw it into the mouth through a glass tube. In some cases even this procedure is too painful. In two instances the patients were successfully fed by means of a nasal tube for nearly two weeks.

One of these was a druggist, forty-eight years of age, who consulted me about five years ago. He had long been a sufferer from trigeminal neuralgia, which had gradually developed into a genuine tic douloureux. When I first saw him, the paroxysms recurred every ten or fifteen minutes during the day, and every half-hour at night. It was impossible for him to chew his food, and he therefore bolted it. The slightest touch upon the face by the finger, the contact of the handkerchief in blowing the nose, or of food in the mouth, would at once excite an attack. The nasal mucous membrane was so sensitive that a soft nasopharyngeal tube could not be inserted without a preliminary application of cocaine. Food and medicines were thus administered for nearly two weeks, with the most remarkable benefit. Under the use of aconitia, in conjunction with rest and good feeding, the attacks rapidly diminished in frequency and severity, and at the end of a week the paroxysms occurred only every hour, and subsequently every three or four hours, until at the end of six weeks he was practically well. It is hardly necessary to mention that such active measures are not required in all cases, but that the means for relief must be adapted to suit the individual.

Relapse is not at all infrequent, and may result from various exciting causes, or be due to the sudden or ill-advised discontinuance of all medical treatment. Hence the subsequent management of these cases requires serious consideration.

Such patients should be kept under medical supervision and direction for a long time after all pain has subsided. It is well to bear in mind that remissions occasionally occur spontaneously, and sometimes a neuralgia that has occurred at intervals for many years gradually ceases as age advances.

The drugs that have been utilized and recommended for the pain are legion, and I will not attempt to enumerate them. While some have survived the tests of careful clinical investigation, the majority have fallen by the wayside and will ultimately pass into oblivion. Among those that have proved indispensable in my experience are morphine, opium, aconitia, the various coal-tar derivatives, cocaine, and nitroglycerin. Quinine, arsenic, and the fluid extract of ergot are all exceedingly useful and remarkably beneficial in neuralgia of a periodic character. There are other drugs and remedial agents that are curative in neuralgia of other parts, but as they are not applicable in this class of cases I have refrained from mentioning them. Neuralgia of the supraorbital branch of malarial origin promptly subsides under the administration of quinine or Warburg's tincture. At least ten or fifteen grains of quinine should be given morning and evening for five or six days. Smaller doses are generally useless. This is preceded by a cathartic dose of calomel, and followed by the use of Fowler's solution of arsenic three times a day, in doses of from three to five drops well-diluted. This should be continued for a few months, unless there is some contraindication. Permit me to mention the following as one of many similar illustrative cases.

Mrs. M. H——, forty years of age, married, has nine children. For the last fifteen years she has had frequent attacks of neuralgia at varying intervals, and always affecting either the right or left supraorbital region. She never vomits. She was seen by me for the first time on January 5th. During the preceding ten weeks and up to the present, there has been severe continuous pain, affecting the left supraorbital region. The attack begins daily at 7 A.M., gradually subsides by noontime, and then disappears, only to return

promptly the next morning. She sleeps well: has never had attacks of "chills and fever." Bowels have been active, as she has taken Rochelle salts daily for many weeks. The pain is getting worse.

On examination the pulse is feeble but regular, and the temperature normal. There is exquisite tenderness over the left supraorbital nerve, and slight tenderness over the right. Examination otherwise negative.

I ordered ten grains of quinine, to be taken night and morning. After the first dose the pain did not appear until noon of the following day and lasted only a few hours. She has had no pain since, but is still under observation. At the end of the first week the dose was reduced to five grains. The blood was not examined.

Opium or morphine is usually the drug *par excellence* for the relief of pain. In neuralgia the judicious use of morphine is preferable, but it should not be employed until other means have failed, excepting to tide over a period of acute suffering, while other measures are being adopted. There are several serious objections to its use, however—the disturbance of the digestive organs and the probability of the "morphine habit" being engendered.

When other methods of treatment have been unsuccessful after a fair trial, I have not hesitated under suitable conditions to order its subcutaneous administration in sufficient dose to insure absolute freedom from pain. The patient should be kept in bed under constant observation, and the general nutrition improved as rapidly as possible.

One of my patients, a woman, fifty years of age, free from evidence of organic disease and a sufferer from this malady, had tried all forms of medical treatment, including aconitia, galvanism, etc., for nearly four years, with comparatively little benefit. She weighed one hundred and eighteen pounds, and her general nutrition was poor. She was kept in bed for over six weeks. During the first three or four days she required six injections daily (given in the arm or thigh), each containing one-sixth of a grain. She was not aware that morphine was being administered. This was gradually diminished, until at the end of four weeks she was receiving but two injections daily, and two weeks later it was discontinued. The pain decreased as her nutrition improved. At the end of three months she weighed one hundred and thirty-five pounds, and made a complete recovery. I saw her a number of times subsequently for about a year, but there had been no return of the pain.

The morphine may often with advantage be injected at the seat of the pain. We need feel no apprehension regarding the "morphine habit" in old people who suffer from tic douloureux, and have obtained no relief by other means. It seems to me that under such circumstances the "morphine habit," if it relieves the patient's pain, is an acceptable substitute for the "pain habit."

The various coal-tar products, such as acetanilid, phenacetin, exalgin, and antikamnia, are more or less useful in mitigating or stopping the pain, but should be utilized only as a temporary expedient, as their continued employment is likely to depresss the vitality by causing anæmia.

The only form of aconitine that has proved exceptionally valuable in my hands is the crystallized aconitia of Duquesnel. This is a very powerful drug, and should be used with caution. Merck's aconitine is less reliable and much feebler in its action, and, on the whole, unsatisfactory as compared with Duquesnel's preparation. In cases that have resisted other forms of treatment, this drug is remarkably efficacious. At first one-three-hundredth of a grain should be given two or three times a day, in order to ascertain if any idiosyncrasy exists.

Women seem to be more susceptible to its influence than men. It may then be given in doses of one-two-hundredths of a grain every three or four hours, preferably when the stomach is empty, and increased according to indications. It is desirable that some of the physiological effects be obtained, such as numbness of the tongue and fingertips. The difference in the action of these two preparations was forcibly brought to my attention a few years ago.

The patient was a bookkeeper, forty-five years of age. I prescribed Duquesnel's aconitia in pills containing one-two-hundredth of a grain, and while taking this dose every three hours he felt very much better. Later, as it became necessary to increase the dose, pills of one-one-hundredth of a grain were ordered, four of which were to be taken daily. Having followed my instructions, he returned in four weeks, asking for a new prescription, so that he could more conveniently get the medicine in his own neighborhood. In order to be more certain that he should receive the genuine preparation, I wrote for pills of one-two-hundredth of a grain, and directed him to take two at a dose. He did not begin the latter until the following morning. At noon I was hastily summoned, and found him in bed, profoundly collapsed and apparently about to expire, with alarming symptoms of aconite poisoning. He had taken one dose at 7 A.M., and another at 11 A.M. With difficulty his life was saved. Upon investigation I discovered that the first druggist had substituted one-one-hundredth of a grain pills of Merck's aconitine, and these the patient had been taking for nearly four weeks, without any improvement in his condition. The last druggist had furnished what was ordered, and thus his system was at once overwhelmed by the doses of one-one-hundredth of a grain of Duquesnel's aconitia. Further comment on the subsequent events in this case is obviously unnecessary.

Cocaine has been injected into the tissue of the alveolar process, and also into the face, but its toxic effects are occasionally so rapid and alarming that I have discarded its use in this manner. In certain individuals it seems to possess some special danger when injected about the head. In some patients the pain is temporarily relieved by the use of cocaine introduced into the tissues of the face by aid of the galvanic current. This procedure is known as anodal diffusion or electric cataphoresis.

A small electrode, connected with the positive pole of the battery, is either dipped into a solution of cocaine, or a small disc of white filter paper saturated with the desired dose is attached to the electrode and applied over the seat of pain. The skin should previously be washed with a little alcohol or chloroform, in order to remove any sebaceous matter. The current is then used in the manner described in the paragraph on the use of the galvanic current. A special electrode has been constructed for this purpose, and other drugs have also been similarly used.

Nitroglycerin, either in solution or in the form of tablets, has often been serviceable, particularly in patients who are over forty years of age, without regard to any marked evidence of increased arterial tension, as indicated by the radial pulse. When the latter condition is present, it is always valuable as an adjunct in the management of these cases, due recognition being given to the cause of the increased blood pressure.

In intractable cases that have resisted other forms of medication, the injection of sulphate or muriate of strychnine into the tissue of the face on the affected side has met with considerable success in a few instances. A daily injection is given, the dose at first being one-thirtieth of a grain. This is gradually augmented to about one-fifth of a grain, or until intolerable physiological symptoms are produced. One of my

patients recently received one-sixth to one-fifth of a grain daily for a week, which resulted in temporary relief, but was discontinued on account of rigidity and cramp in the cervical and calf muscles. This form of treatment should always be accompanied by rest and the administration of abundance of nutritious food.

Iodide of potassium in increasing doses, in conjunction with the administration of aconitia, has been the means of relieving and also curing quite a number of otherwise intractable cases. Just as large doses of quinine are sometimes effectual in non-malarial cases, so iodide of potassium has proved remedial in the absence of all evidence of syphilis.

I have often found galvanism exceedingly serviceable in diminishing or abolishing the pain, especially in early cases. The current strength may range from five to ten milliampères, and the *séance* last from five to ten minutes daily, or twice a day if indicated. It is essential that a rheostat and meter be included in the circuit. The current should be very slowly increased from zero to the amount desired, and allowed to flow at the same degree without interruption, until the time for cessation, when it should be gradually decreased until zero is reached, before the electrodes are removed from the skin. I have been accustomed to apply the positive pole over the painful area. The induction current from a static battery, applied directly to the face, has in two or three cases produced considerable amelioration.

If a local cause of the pain is discovered and seems removable, this should be accomplished without unnecessary delay. Consequently it often becomes imperative to seek the counsel and assistance of the ophthalmologist, laryngologist, or dental surgeon, whose special qualifications make their services of inestimable value, both to the attending physician and the patient.

The importance of studying the habits and constitutional condition has already been referred to, but is deserving of emphasis. Whatever is ascertained must receive the careful and methodical attention that its nature demands. I shall not dwell any further upon this matter, as such details in general management may usually be left to the good judgment and discretion of the practitioner. In this connection let me call to your notice the case which prompted the writing of this paper.

Miss J. L——, twenty-seven years of age, consulted me for the first time on the 20th of last October. Four years ago she began to have pain in the right side of the face, with intervals of abatement for three or four weeks. Within the last two years and up to the present time, it has been constant. The pain is limited to the distribution of the second and third branches of the right trigeminus, extending to the tip of the tongue and the chin. Paroxysms occur every ten or fifteen minutes, and are accompanied by a profuse flow of saliva, which terminates the attack. The pain is excited and increased by talking, eating, blowing the nose, etc. It also occurs during the night and disturbs sleep. She complains of constipation and flatulent dyspepsia. Menses are regular. Although six teeth have been extracted from the right lower jaw, the pain has persisted. There is no history of rheumatism, syphilis, etc., traumatism, or exposure to cold, to account for the origin of her trouble. She had been advised to have the nerves removed by surgical operation.

Upon examination the paroxysm is produced when pressure is made over the toothless alveolar processes. There are no other painful points. The tongue, which is protruded well, is tremulous, thickly coated, and a few superficial ulcers are seen on the border of the right side. The breath is very offensive. Stomatitis, which has existed for many months, is quite pronounced. The gums are tender and soft, and bleed readily upon the slightest touch, the condition being very suggestive of a scorbutic gingivitis. The saliva shows a distinctly acid reaction. Pupils and ocular fundi normal. Pulse, 76 and regular, but somewhat weak. Heart's action and other organs normal. Examination of urine negative.

The mouth was cleansed and a one-per-cent. solution of nitrate of silver applied daily. An alkaline, antiseptic mouth wash was used every half-hour, and absolute cleanliness enjoined. Subsequently peroxide of hydrogen was applied, and later an astringent solution. She was instructed to avoid unnecessary talking and to have fluid diet only, consisting of milk, eggs, meat juice and pulp, and the juice of two lemons daily. She also received maltine with cascara sagrada, and later this was changed to one drachm of phosphate of sodium in solution on arising. The galvanic current was applied daily. After three days she slept well every night, and at the end of a week she had only occasional pain during the day. The tongue gradually cleared and the stomatitis subsided. She is still under observation, and is very much improved.

This case, it seems to me, clearly illustrates the advantage of careful and systematic treatment. Such prompt relief without the use of anodyne drugs is not at all unusual, when local measures are supplemented by judicious management of the general health. This young woman had previously obtained no relief from symptomatic remedies, and her physician had consequently advised surgical intervention.

Just here let me say a few words regarding the recklessness and unwarranted haste in advising surgical operation upon the nerve. I regret to admit that within a few weeks several cases have come to my notice, and many others in recent years, in which, the patient demanding relief and the physician either becoming impatient or discouraged, surgical measures have been recommended, although the duration of the affection was but six or eight weeks.

There seems to be a deeply rooted opinion that in all cases that have resisted the canonical forms of medicinal treatment, recourse must be had either to operation upon the deep branches of the nerve, or excision of Meckel's or the Gasserian ganglion, or to the systematic use of morphine to make life endurable. Before advising or consenting to surgical operation, I must feel satisfied that suitable thorough and persistent treatment has proved ineffectual under competent observers. As there is possibility, nay, even great probability of relief in most cases of tic douloureux and chronic trigeminal neuralgia without surgical operation, the latter should be seriously considered only as a *dernier ressort* or after all available resources have been exhausted.

959 Madison Avenue, New York.

Diagnosis of Carcinoma of the Breast in Its Early Stages.—Dr. A. Marmaduke Shiel, in a clinical lecture on this subject, emphasizes the following points: (1) The age; the most likely age is between forty and forty-five. (2) The character of the pain, which is neuralgic, not throbbing, and is not accompanied by heat or redness. (3) The onset is insidious. (4) The contour is rarely globular: usually it is obtuse or irregular. (5) The hardness is stony, and is one of the most striking and reliable characteristics of scirrhus. (6) The growth does not move in the breast substance, but moves with it. (7) Retraction of the nipple is an important symptom, but it may be absent. (8) The dimpling of and the pig-skin-like condition of the skin are of the utmost value. (9) The presence of enlarged glands is important, but their absence is not proof that the disease is innocent.—*International Medical Magazine.*

RESULTS OF (CHEMICAL) ELECTROLYSIS VERSUS DIVULSION OR CUTTING IN THE TREATMENT OF URETHRAL STRICTURES.[1]

By ROBERT NEWMAN, M.D.,

NEW YORK.

The writer has practised with success electrolysis in the treatment of urethral strictures just thirty years; he reported his first cases in 1872, and established his improved method with appropriate electrodes in 1874. Among his first followers was Dr. John Butler, of this city, who, like many others, used a too strong electric current. The same gentleman constructed a new instrument for electrolysis, which acted partly like a divulsion, and soon was given up by him. Dr. Butler has described his instrument in the *American Journal of Electrology and Neurology*, New York, vol. i., No. 2, October, 1879, p. 95. On examination the instrument will be found almost identical with that of Fort, of which he says himself: "I invented and have been using the electrolyzer for the last fifteen years, or, in other words, since 1881."[2] Butler's instrument consists of a hollow tube, entirely insulated, having a slot, in which are concealed one or two wires, which can be made to separate or protrude, so as to form an ellipse, by turning the nut from left to right. This ellipse, owing to the great flexibility of the wires, adapts itself to the shape of the stricture. There is a groove and eyelet in the tip *b*, to allow the use of a filiform guide. He had some made short and straight for operating on the dependent portion of the urethra; and still others with one active wire, the one not intended to be used being insulated.

Now let us examine Dr. Fort's electrolyzer. It differs from Butler's instrument only in the projecting platinum blade near the tip, which is fixed permanently and cannot be regulated to adapt itself to the size of the stricture. The same projection is used for every stricture, no matter whether the calibre is small or large. Neither instrument can be used in strictures of small size, as it is necessary for the tip to enter the stricture—which tip is about like a No. 12, French scale. As the size of the instrument at its projecting blade is equal to a No. 23 French, the operation must necessarily make an enlargement from at least No. 12 to No. 23—which is a difference of eleven numbers. This objection, however, can be obviated by having instruments of different sizes. Dr. Fort says, in the same article quoted above: "The operation, as a rule, lasts from twenty to thirty seconds." In a former paper, he states that a galvanic battery is used with a current of at least ten milliampères, but omits to say what the strongest current he may use is. Now the question arises, Can a current of ten milliampères for thirty seconds enlarge a stricture eleven numbers, or even less, by electrolysis, or is the enlargement due to the force used, thereby being a divulsion? To ascertain what electrolysis really does, two experiments were made.

Experiment I.—A solution of iodide of potassium was divided in two equal parts. One part was submitted to Dr. Fort's procedure, a current of ten milliampères for thirty seconds, and the result you see here in this bottle marked "A." The other part was treated in the same way by five milliampères for ten minutes, the treatment at one *séance* for stricture by the author's method. Bottle marked "B" shows the result.

Experiment II.—On a mucous lining of a pig's bladder Fort's instrument was used, with a current of ten milliampères for thirty seconds; the result you will find here marked "C." On another part of the same mucous lining five milliampères were used for ten minutes, the writer's method; the result is marked "D." This experiment is made only to show that the electrolysis used does not burn or destroy tissue. Electrolysis used on a healthy mucous lining is not intended to prove the action on a stricture, which is a pathological condition of the mucous lining.

Patents of Instruments by Physicians.—Reliable information reports that Dr. Fort has patented his instrument. It is still a mooted question whether the present rule of the medical code in regard to the patenting of instruments is just. A true humitarian gives his invention free to the millions. He may be bothered in many ways. Competition of instrument-makers will soon throw an inferior article on the market, with the name of the inventor, a lower price, and probably with a so-called improvement by the instrument maker. The good manufacturer cannot sell his superior instrument, the article sold is bad, and the inventor cannot recognize his own child; it will not fulfil its requirements. This inferior instrument will bring the operation of the inventor into discredit, and the whole work of the inventor is soon condemned by the profession. Still worse, an enterprising manufacturer patents a good invention, and prevents the real inventor, who thought that the code of medical ethics made him a benefactor of humanity, from using his own instrument. It seems that the code needs an amendment to protect an inventor, so that he can guard against the falsification of his own instrument, without really gaining by the manufacture of the article. An inventor wants to see that his ideas are carried out by the manufacturer in making a good instrument. This will protect his reputation, without yielding him any profit.

Dr. R. W. Taylor's Remarks.—On November 12, 1895, at a meeting of a section at the New York Academy of Medicine, Dr. Robert W. Taylor, in introducing Dr. J. A. Fort, of Paris, made several statements as follows:[1] "I need not say anything about the fallacies and want of success of the method of electrolysis which has been in use in America for many years. In Newman's method of electrolysis, the instrument, with a round, olivary tip, was passed down the stricture, and the mucous membrane was burned away as well as the stricture."

Why Dr. Taylor has made such misleading statements is difficult to understand. To explain again the theory and practice of electrolysis in the stricture of the urethra, and thus show how incorrect Dr. Taylor's statements are, is one reason for preparing this paper. In December of 1890 the writer had the honor to read a paper before this association, on "Twenty Years' Retrospect in the Treatment of Urethral Strictures by Electrolysis," which was published in the *Journal of Electro-Therapeutics*, New York, January and February, 1891, describing the method and the success of that treatment. Remarks as quoted above prove, however, that some of the profession do not understand the modes advocated, making it an imperative duty in this paper to elucidate again the theory and practice of electrolysis.

The Theory of Electrolysis.—Electrolysis as a chemical action is an acknowledged fact since 1800; the theory can be found in any text-book on elementary physics and chemistry. Electrolysis is the decomposition of a compound body by electricity—a chemical decomposition. "Thus, since an ampère is a current of one coulomb per second, and each coulomb of electricity passing through a solution of silver deposits 1,118 milligrams of silver, a current

[1] Read at the meeting of the New York County Medical Association, March 15, 1897.

[1] American Medico-Surgical Bulletin, December 1, 1895, p. 1,452 and 1,453.

strength of one ampère produces a deposit of 1,118 milligrams of silver per second."[1]

In the treatment of urethral strictures by electrolysis we depend in principle on the action of a galvano-chemical absorption. It has been asked, what absorbs what? The answer is that the decomposition of the electrolytic current by its decomposition absorbs by degrees the pathological formations of the stricture; or, in other words, the decomposition absorbs the fibrous tissues which have encroached on the calibre of the urethra, and by such absorption the calibre will be freed from the obstruction and finally restored to its normal size and healthy tissue.

A stricture is always a consequence of an inflammation, which may come from different causes, mostly a long-continued suppuration, which forms infiltration not only in the mucous lining, but deeper in the submucous tissues. Fibrous tissues or cicatrices thereby formed infringe slowly on the calibre of the urethra, and multiply in time to such a degree that no room is left for the passage of the urine. In form and size strictures may vary, and, if they are only on one side of the urethra, or due to a contraction or malformation of the mucous lining, they may be cured by the usual means practised in genito-urinary surgery—gradual dilatation, divulsion, or cutting operations. However, most strictures are equally spread in a circle around the normal calibre of the urethra, and in those cases electrolysis promises better results as a curative measure, theoretically and practically.

From experiments on tumors, the writer has demonstrated and seen that a needle inserted in a tumor exerts an electrolytic action around itself in a radius of from one to two inches, and absorbs thereby the pathological tissues. Fibroid tumors, particularly in the practice of gynæcology, have been reduced in size and sometimes absorbed entirely by electrolysis.

The cutting operation for stricture can only divide the obstruction in one line and in one place, leaving the other parts of the constriction intact. Even if an incision enlarges the calibre, one of two things will follow: Either the divided surfaces come in apposition and then heal by first intention, thereby restoring the stricture just as it was before the operation; or the divided surfaces are kept apart and stretched, in which case the healing must take place by granulations and subsequent formation of cicatrices, leaving the patient uncured and in a condition still requiring the use of a sound. This is admitted even by the principal advocates of cutting operations.

Many voices in the profession have protested against urethrotomy, and such have been mentioned by the writer in former papers; for instance, Dr. J. H. Girdner.[2] Dr. J. P. Tuttle[3] said, at the meeting of the New York County Medical Society, May 25, 1896, that the whole principle of dilatation and internal urethrotomy was wrong. The success of internal urethrotomy depended, not upon the thoroughness of the cutting, but upon the thoroughness with which the urethra was dilated after the internal urethrotomy. Dr. N. Senn declares cutting operations in strictures a failure, in his essay at the New York State Medical Association, held October 28, 1891.

The statement of some eminent practitioners, that in Newman's method of electrolysis "the mucous membrane was burned away as well as the stricture," is absurd and incorrect, to say the least. These gentlemen ought to know that an electric current of from three to five milliampères cannot possibly burn, cauterize, or destroy a mucous lining. If they do not know this, the writer has told them privately in conversation, as well as in his published statements, that strong currents which cauterize must be avoided: that he depends entirely on the electrolytic action of absorption, which does not destroy the mucous lining, but affects the new formation. In the meeting mentioned above, Dr. W. J. Morton was the only one who said that "Dr. Taylor was not quite fair to Dr. Newman, in stating that the latter burned his way through the stricture, for certainly Dr. Newman distinctly states in his writings that mild currents are used," etc. There is absolutely no burning or destruction in the mucous lining by the writer's method of electrolysis, and he refers again to his writings and also to the results of his experiments in electrolysis on dogs,[4] that were treated by a stronger current and nevertheless recovered in good shape. Even if a mucous lining is injured by caustics, it would recover itself, as we see in gynæcological practice, and Dr. I. A. Taylor has in his operations demonstrated this fact to the class of Bellevue Hospital Medical College.

The way a cure by electrolysis is effected is as follows: A No. 11 French electrode connected with the negative pole of a galvanic battery is introduced to the stricture; three, four, or even five milliampères are used; the electrode is held on the stricture (guided but no force used) till the absorption allows the electrode to pass and be easily withdrawn. After one week the operation is repeated with a No. 14 French electrode, egg shaped, using a current of from three to five milliampères for about ten minutes. Each week a *séance* follows with a larger electrode, till the stricture is absorbed and the calibre of the urethra restored to its normal size.

The Practice.—In theories individuals may differ, and all theories are not confirmed by practising; but if the practice is successful it makes the theory correct, and proof of success in practice confirms the theory.

This is our case under consideration, and from reliable reports the treatment of urethral strictures by electrolysis has been a decided success, as will be seen by the following history.

The writer has treated urethral strictures by electrolysis for thirty years, with success, without any relapse; has written many reports on it; particularly given *in extenso* three hundred cases, in series of one hundred each. He read a paper before this association on December 15, 1890.[5] His next paper was read before the American Electro-Therapeutic Association, in October, 1892, in New York,[6] "On the Present Status of Electrolysis in the Treatment of Urethral Strictures, with Statistics of One Hundred Cases" (the third series). The writer next reported seventeen hundred and fifty-five successful cases by fifty-four different operators, all of whom vouch for the correctness of their statistics;[7] and additional cases by Drs. G. Howard McFadden, F. H. Wallace, W. R. D. Blackwood, C. A. Bryce, etc. On April 14, 1893, Dr. A. R. Booth, of Shreveport, La., reported one hundred more successful cases. In June, 1893, Dr. F. B. Bishop,[8] of Washington, D. C., reported more successful cases. Dr. H. E. Bennett,[9] of Lima, Ohio, in an article on strictures, speaks favorably of Newman's method. Dr. Fred S. Crossfield, of Hartford, Conn., reported one hundred successful cases.[10] To dispel any possible doubt about the correctness of the statistics, a committee of investigation was appointed by the American Electro-Therapeutic Association, who

worked faithfully for a whole year, and finally reported [1] as follows:

On Investigation of Dr. Newman's Statistics.—"We have examined the records of Dr. Newman's cases of urethral stricture submitted to us, and regard his conclusions as well sustained by the statistics he has presented, and as far as our experience in this line of work adds further testimony, it is confirmatory of the value of the continuous current in resolving a large class of urethral strictures. The committee made diligent efforts during the year to comply with the directions given them, to enlist the co-operation of surgeons of large experience in other methods of treatment of urethral stricture in examining both the patients and statistics, but failed to receive such assistance from them." Chicago, September 11, 1893. Signed by A. H. Goelet, William J. Morton, W. J. Herdman.

On motion the report was accepted.

More good reports come from Dr. G. W. Overall, of Memphis, Tenn. Cases 83–87, in 1894.

Dr. Lamoureux read a paper in Lowell, Mass., August 29, 1895, and reported twelve successful cases. Another favorable report was made by Dr. M. H. Sears before the Denver (Col.) Medical Society.[2] A very good article was written by Drs. Holladay and Burton, of Hot Springs, Ark., on "Urethral Strictures, Treatment by Electrolysis."[3]

Dr. Desnos, of Paris, reviewed the different methods of electrolysis in strictures of the urethra,[4] before the Société Médico-Chirurgicale, in Paris, February 10, 1896, in which he gave the Newman method the preference. At the annual meeting of the American Electro-Therapeutic Association, in Boston, two more papers were read, on October 1, 1896, on successful treatment by Newman's method, by Dr. F. H. Wallace, of Boston, and Dr. F. B. Bishop, of Washington, D. C.[5]

In an article on "Electricity as Applied to Medicine and Surgery," Dr. Fred Schavoir, of Stamford, Conn., says: "I consider electrolysis for urethral strictures one of the greatest triumphs in electro-therapeutics."

The Correct Diagnosis.—The writer had very little to do with the diagnosis in the cases he reported, because most of the patients had been under treatment many years and the diagnosis had been made by one or more eminent genito-urinary surgeons, who generally advised cutting operations; other patients were sent for the electrolytic treatment by well-known eminent practitioners. Only recently a patient's stricture was so contracted that his physicians could not pass any instrument. Therefore, as a last resort, the parts were anæsthetized and two physicians tried to pass a small catheter, without success. As the patient became conscious he overheard the conversation of the two surgeons, in which they said they were unable to pass any instrument, and that there might be a chance for him by Newman's method of electrolysis. When he was fully recovered these gentlemen told him that he must undergo a cutting operation within twenty-four hours, otherwise they could not guarantee his life. They never mentioned electrolysis to him. The patient found his way to the writer, electrolysis passed a No. 9 instrument immediately through the stricture into his bladder, and a few months later a No. 21 French passed. It was a very bad stricture, indeed. Such cases have appeared often, and have been reported in former tables published. Relapses have not taken place after patients had been discharged as cured, and they have been kept under observation for many years. Only recently a patient was seen well, without a day's sickness, twenty years after he had been treated by electrolysis for strictures. In most cases when opportunity offered re-examinations have been made. These facts have been explained more in detail in former papers. Some patients have appeared again after six or seven years, complaining of a relapse, but on examination no relapse was found, and the ailment was a new one in a different place.

Reliability of Reports.—The statements as reported have been made from actual facts as recorded in notebooks, from letters of patients and physicians, as also from testimonies, observations and re-examinations, documentary evidences, etc., and all these points have been carefully investigated during a whole year and found correct by the committee mentioned above and have been certified accordingly.

Now about failures which have been reported, and must be considered also as facts. Undoubtedly operators have failed, and the cause lies between the operator's incompetency, carelessness, impatience, mismanagement, wrong diagnosis, faulty instruments, and the patient's disobedience—all of which may occur in any operation.

The success of electrolysis in urethral strictures is so well established that simple negations cannot undo affirmations and facts of success, as found true by investigations of reliable medical gentlemen.

Conclusions, which are for your consideration and discussion:

(1) There is a similarity in the construction of Butler's and Fort's instrument, the priority of the idea belonging to Butler.

(2) The current of ten milliampères can give very little, if any, electrolytic action in thirty seconds; therefore Fort's operation, called "linear electrolysis," is in reality a divulsion.

(3) The present code does not protect a physician as an inventor, nor his instrument.

(4) The success of electrolysis in the treatment of urethral strictures is a fact well established by documentary evidence and by the thorough investigation of an impartial committee.

(5) A current of five milliampères cannot burn, cauterize, or destroy normal tissues.

(6) Relapses do not occur if the subjects are cured once by electrolysis proper.

Retroversion of the Uterus.—Martin (*Journal of the American Medical Association*, February 20, 1897, p. 335) summarizes as follows his views upon the question of retroversion of the uterus: (1) Continuous retroversion of the uterus is a condition that frequently leads to serious pathologic consequences. (2) Retroversion without adhesions can be cured without operative interference in about twenty per cent. of the cases in which it occurs. (3) A small percentage of cases of retroversion with adhesions can be cured by massage, electricity, and depletion. (4) Retroversion with unyielding adhesions should be corrected through Douglas' cul-de-sac and the round ligaments should be shortened at the same operation. (5) Retroversion with diseased appendages should be treated through an abdominal incision and the uterus brought forward and suspended from the urachus or from a ligament constituted of peritoneum. (6) When the Alexander operation is performed, the ligaments should be secured without resort to a permanent buried suture, and this can be best accomplished by tying the two ligaments together in a firm knot over the pubes beneath the integument.

Progress of Medical Science.

The Sterilization of Catgut by Cumol.—Drs. Clark and Miller, after a thorough bacteriological investigation and a practical experience of a year with the cumol method of the sterilization of catgut, conclude that it is the most reliable. They state that many of the methods hitherto practised are unreliable, as has been shown by the outbreaks of infection which have been traced, either by direct bacteriological investigation or by the strongest circumstantial evidence, to the catgut used in the cases. Catgut received from the manufacturer is rarely infected with pyogenic organisms, which accounts in a great measure for the absence of infections following its use when prepared by the most questionable of methods. At least three outbreaks of infection in surgical cases have been attributed to catgut. The first, in 1879, in the service of Zweifel, was certainly traced by Koch to the suture material by a careful bacteriological study. Kocher, in 1881, after a very superficial study of the germicidal power of juniper oil, introduced it as a sterilizing medium. Later, a large number of cases in his hospital service became infected, and Kocher, feeling that he had such strong evidence against the catgut employed in the cases, published an article against its use in any form, entitled "Away with Catgut." In January, 1893, a very serious reign of infection occurred in the gynæcological wards of the Johns Hopkins Hospital, which was believed to be due to catgut prepared by boiling in alcohol under pressure. The most perfect means of sterilization of catgut for surgical purposes is, unquestionably, by heat. Until the methods of Benckisser and Reverdin (1881), it was considered impossible to raise any form of animal ligature material to a temperature sufficient to render it sterile without making it brittle. Reverdin demonstrated that it was not the oil, as previously supposed, but the hygroscopic property in catgut which caused it to become brittle when heated. If this is driven off by dry heat at a temperature of 70° C., the catgut can safely be exposed to a temperature of 250° C., without impairing its integrity. The complicated apparatus, consisting of a hot-air oven and a thermoregulator, however, prevented the general adoption of the methods of these writers. Brunner found that the boiling-point of xylol was 136°–140° C., and at once adopted it as a sterilizing medium, but Krönig found spores occasionally present in catgut which were more resistant than the anthrax spores with which Brunner had experimented. After a further research Krönig found that the boiling-point of cumol, a hydrocarbon compound, ranged between 168° and 178° C., and substituted it for xylol. After a careful review of the Krönig's article, his method was adopted in the gynæcological department of the Johns Hopkins Hospital. Krönig's method is as follows: (1) Roll the catgut in rings. (2) Dry it in a hot-air oven or over a sand bath for two hours at 70° C. (3) Heat it in cumol to a temperature (165° C.) a little short of the boiling-point, for one hour. (4) Transfer it to petroleum benzin for permanent preservation, or, if desirable, leave it in benzin for three hours, and transfer to sterile Petri dishes. A bacteriologic study of this method by the writers shows that the sterilization by this method is perfect, but that the transference from boiling cumol to benzin is open to serious objection. Clark and Miller have found from this investigation that benzin is not a germicide; also that it cannot be rendered sterile by heat without danger, and, therefore, have found it necessary to modify the method of Krönig as follows: (1) Roll the catgut, twelve strands, in a figure-of-eight form, so that it can be slipped into a large test tube. (2) Bring the catgut up to a temperature of 80° C., and hold it at this point for one hour. (3) Place in cumol, which must not be above 100° C., raise it to 165° C., and hold it at this point for one hour. (4) Pour off the cumol, and either allow the heat of the sand bath to dry the catgut, or transfer it to a hot-air oven, at a temperature of 100° C., for two hours. (5) Transfer the rings with sterile forceps to the test tubes previously sterilized, as in the laboratory. In drying or boiling, the catgut should not come in contact with the bottom or sides of the vessel, but should be suspended on slender wire supports, or placed upon cotton loosely packed in the bottom of the beaker glass.—*Johns Hopkins Hospital Bulletin.*

Cyclic Albuminuria.—Dr. Marie defines this disease as albuminuria occurring in apparently healthy subjects, being intermittent in its course and subject to certain conditions. The discovery of albumin may be accidental or the patient may suffer from general debility, heaviness of the limbs, palpitations, headaches, and hemorrhages. Healthy persons may have transitory albuminuria under certain conditions. Hwass found albumin in ninety-eight out of six hundred and thirty-five apparently healthy soldiers, the quantity of which was not influenced by exercise. Captian and Spiegler found albumin, probably from reflex causes, always present in one hundred cases of scabies. This transitory must be distinguished from true cyclic albuminuria. It is doubtful whether cases which are influenced by food or cold are examples of this disease, or in perfectly typical cases they have often no effect. The cardinal symptom is that albumin is present only when the upright position is assumed, and vanishes when the patient lies or sits down, even when hard work is done on an exercise apparatus. In the case reported by the author, however, albumin appeared sometimes when the patient was in bed, at times of great annoyance or in stormy weather. The quantity of albumin is always small. Its chemical composition varies with the individual and in the same individual at different times. Serum albumin, peptone, propeptone, nucleo-albumin, etc., have been found. The quantity of urine is not much affected. If at any time it is less than normal, there is said to be a corresponding increase in the albumin. The specific gravity varies, but is usually normal or higher (1.020 to 1.030). Teissier gives the following cycle in this disease: (*a*) plus excretion of coloring matter, (*b*) albuminuria, (*c*) plus excretion of urates, (*d*) plus excretion of urea. Etiology: (1) Sex, more common in females. (2) Age, adolescence and early adult life. (3) Heredity, especially in children of gouty and arthritic parents (Teissier). (4) Disputed antecedents are renal affections, colds, overwork, and infective fevers. The author states that he considers it to be a special morbid entity, probably depending on perverted function of sympathetic nerves, and having a close analogy to migraine. He does not agree with those who believe the cause to be a "minimal" organic renal lesion, as the almost indefinite time the disease can last without bad effects and its not being influenced by the quality of the food are against that theory. Casts are not generally present, but Marie does not consider that the presence of casts in small numbers indicates organic disease.—*La Semaine Médicale.*

A Method of Disinfecting the Blood in Serious Infectious Diseases.—A contribution to this subject has been made by Dr. Henri Barré. The process to which he has given the name "disintoxication of the blood" is derived from simultaneous employment of two therapeutic means already made use of in medicine: the one very ancient, bleeding; the other very

modern, the intravenous injection of artificial serum. The aim of this treatment is to combat the phenomena of general intoxication which manifest themselves in the course of or toward the end of many diseases, and which in themselves put in peril the life of the patient. Before this treatment is begun there ought, of course, to be brought to bear the ordinary methods at the disposition of the physician—purgatives, diuretics, stimulants, sedatives, etc.—and it is not until the insufficiency of these is evident that as a last resort recourse is to be had to "disintoxication of the blood." This is most often indicated in the following maladies: uræmia, eclampsia, diphtheria (when Roux's serum does not suffice), infectious pneumonia, capillary bronchitis, malignant icterus, general acute peritonitis, cerebro-spinal meningitis, typhoid fever, measles, small-pox, scarlet fever, puerperal fever, cerebral complications of rheumatism and gout, poisoning by alkaloids, extensive burns of the skin, etc.; in short, in all cases in which there may be expected danger as much or more from general intoxication as from actual lesions of the organs themselves. In all these diseases there is to be noted a considerable diminution, if not a complete cessation, of the urinary function, and the disintoxication of the blood has for its immediate purpose (1) to eliminate artificially a certain quantity of toxins; (2) to help to achieve complete elimination by re-establishing the secretion of urine. The instruments necessary consist essentially of two india-rubber tubes, terminating at their extremities in a needle of a diameter a little greater than that of a Pravaz syringe. The longer of these tubes (about one and one-half inches) conducts into the veins of the arm the artificial serum from a graduated vessel placed at a position more or less elevated in accordance with the degree of force with which the flow of liquid into the venous system is required. The second tube (one metre), of which the needle is inserted in a vein of the other arm, has its free end in a graduated vessel, and thus serves to extract blood. The flow of the two liquids by this arrangement can be so regulated that no more serum enters than blood flows out, and thus, the circulatory system being always equally full, arterial tension need not be diminished, as it is as a consequence of ordinary bleeding. The quantity of serum introduced and the quantity of diluted blood withdrawn may vary between fifty grams and one litre for an adult, in accordance with the degree of intoxication. As will be seen, this method of disintoxication of the blood differs materially from another method, which has been styled "washing the blood," and which has been for some time applied by preference in cases of surgical infection. The difference consists mainly in the contemporaneity of the injection and the bleeding. This prevents any severe interference with the circulatory system, and allows, if death from intoxication seems imminent, the withdrawal of the greatest quantity of blood, and consequently disintoxication with the least danger to the patient. The exchange of liquids is made very quickly (in thirty to fifty minutes), so that no sharp reaction ensues; grave symptoms insensibly diminish, gradually disappear, and are followed soon by refreshing sleep. On waking, the patient desires to pass water. Sometimes sweating accompanies the re-establishment of urination, as in natural crises. In the three cases (two of uræmia, one of infectious pneumonia) in which Dr. Barré has applied his method, cases in which everything had proved useless and in which death appeared imminent, he obtained improvement as rapid as that just described. Not only did the most serious symptoms cease, but at the end of the urinary crisis they did not reappear and the patient progressed steadily toward cure. Dr. Barré expounds the following theory to explain the phenomena of the cure: (1) There is elimination of the excess of toxins, which constitute the immediate danger. (2) The good effects continue because the bulk of blood is not diminished in volume in the system and does not need reforming at the expense of the fluids of the economy, and, the arterial pressure not being diminished, no obstacle to diuresis is created. (3) Not only are toxins eliminated which appear to have an inhibitory action on the urinary action, but the toxins which remain become diluted and less powerful for evil. (4) As recent researches have proved, the alkaline salts have a favorable action on the bactericide powers of the blood, and the method thus provides the economy with a new means of fighting successfully against the microbes. Dr. Barré believes the method will be found of enormous advantage in veterinary as well as in human pathology.—*Medical Press.*

Tinnitus Aurium.—Drs. Miot and Herck divide sounds in the ears into two groups: (1) The noises which really exist in the ears or their neighborhood. They are called entotic and periotic sounds respectively. (2) The true tinniti or auditory sensations which have no apparent cause. In the first class are many conditions. It may be an increased resonance of the ear or hyperæsthesia of the auditory nerve, which make the individual more sensitive to sounds. The sounds may be due to an increased flow of blood through the ear. Muscular contraction and mucous plugs in the external ear causes noises also. The authors recognize two varieties of true tinnitus: (*a*) The noises due to a lesion of the auditory apparatus. (*b*) The noises due to nervous diseases, mental disorders, and reflexes, without any lesion of the ear organs. Middle-ear diseases cause tinnitus, especially in cases of circumscribed or diffuse otitis. In this case the tinnitus is caused by a hyperæmia of the region. In the middle ear various conditions of the tympanum and Eustachian tube give rise to tinnitus. Inflammation of the mucous membrane of the middle ear with secondary hyperæmia of the labyrinth is a frequent cause. Local applications of cold and local bloodletting, combined with catheterization of the Eustachian tube and insufflations of medicinal vapors, give the best results in this condition. Catarrh of the middle ear causes tinnitus. Irrigations through the tube is the best treatment in this condition. If the discharge becomes very great, it must be removed through an incision in the tympanum. Chronic otitis media is a very common and persistent cause of tinnitus aurium, and the authors say the subjective noises resist all treatment. Otorrhœa of a tympanic or labyrinthine origin is a frequent cause of tinnitus, and when the discharge is in the semicircular canals, as in Ménière's vertigo, the noises are extremely violent. The tinniti caused by lesions without the auditory apparatus are of various kinds. In many diseases of the nervous system, the subjective noises in the ears are premonitory or accompanying symptoms: apoplexy, cerebral anæmia and congestion, cerebral softening due to arteriosclerosis in the aged, paralysis, etc., are ushered in by unusual noises in the ears. Nicoti and Rabioli have described an auditory migraine. In some mental diseases tinniti are prominent. False auditory perceptions are common in the insane: and in the same cases there are auditory hallucinations and confused noises.—*Bulletin Médical.*

Sensory Disturbances in Locomotor Ataxia, and Their Location.—Some years ago the subject of locomotor ataxia was thought to be practically exhausted, the symptomatology and pathology clear; the disease was labelled and put away upon the nosological shelf. More recently the question of its pathology has been awakened afresh and is not yet settled, and additions

to our knowledge of its symptomatology are far from infrequent. Such an addition we may count the investigations of Laehr regarding the occurrence of anæsthesia upon the trunk. It is about two years since Hitzig called especial attention to this symptom, but the work of Laehr is the fullest and most systematic up to date, embracing as it does the careful, often-repeated examination of sixty cases of locomotor ataxia. In only five was there no anæsthesia of the trunk, and these five were all cases of locomotor ataxia complicating dementia paralytica, in which the spinal affection was secondary to and much less prominent than the cerebral affection. This trunk anæsthesia is usually not very marked, and relates particularly to the perception of touch rather than pain, in contradistinction to the sensory disturbance of the lower extremities, which ordinarily first manifests itself as an analgesia, while sensation for touch is normal. Its location is generally at about the level of or just below the nipple, and takes the form of a band reaching from the spine to the middle line in front. It is nearly always bilateral, but the bands of the two sides may not be of the same width nor on the same level. Want of symmetry is generally due to the anæsthesia of one side extending lower, as the upper border seldom differs on the two sides. In the incipient stage the band is narrow, taking in one or two intercostal spaces and their borders, or the anæsthesia itself may not be constant. Indeed, in this stage there may be no distinct anæsthesia, but simply an inability to locate touches well, while the power of localization is often found in the area adjoining a distinctly anæsthetic surface. When the anæsthesia is very slight, a prolonged examination of touch and pain sensation may improve it, so that the anæsthetic area diminishes in size. One of the most interesting facts elicited by Laehr's investigations is that the areas of anæsthesia correspond closely, not to the peripheral nerve distribution, but to the spinal segments, as outlined by the work of Thorburn, Starr, Sherrington, Head, and others. The band about the trunk has a more horizontal position than the ribs, so that if it corresponds to a certain rib in front it falls one or two vertebræ below it behind. In some cases the author could watch the gradual extension upward of the anæsthetic zone. With great regularity, as soon as it reached the third intercostal space, it began to extend on to the arm, at first affecting only the inner surface below the axilla, and then gradually covering the whole inner border before it spread much toward the radial side. Eventually the whole arm may become anæsthetic, but always by this extension from the ulnar to the radial side. As already mentioned, this corresponds to the gradual upward invasion of spinal segments, and a similar progression downward on to the lower extremities could also sometimes be traced. But it is not to be forgotten that a peripheral neuritis, which is now known frequently to occur in locomotor ataxia, may entirely change this distribution of anæsthesia. Analgesia of the ulnar trunk—that is, absence of pain when it is pressed against the condyle—he finds to be much less frequent (sixteen in forty-three) than did Biernacki (fourteen in twenty), who first described it. (The editor has found it in fully fifty per cent. of his cases.) It is of interest, too, to note that the author found in a number of cases entirely distinct bands of anæsthesia corresponding to spinal segments separated by a considerable interval, which would seem to show that the pathological processes of locomotor ataxia may begin at nearly the same time in different parts of the cord. Another interesting fact is that at the border of the anæsthetic zone the skin is often hyperæsthetic to pricking, pinching, and cold, and not only this, but in this hyperæsthetic zone the cutaneous reflexes are particularly lively. Laehr thus easily accounts for the difference of opinion regarding the activity or absence of the superficial reflexes in locomotor ataxia. If the place we stimulate to elicit a superficial reflex (*e.g.*, the abdomen for the abdominal reflex, the inner surface of the thigh for the cremaster reflex) happens to be within the anæsthetic zone, the reflex will be diminished or lost; if within the hyperæsthetic zone it will be exaggerated. The author considers the trunk anæsthesia to be a very early, but not the earliest, sensory disturbance, as some degree of analgesia of the lower extremities generally precedes it.—*Medicine.*

Early Diagnosis of Coxo-Tuberculosis.—Dr. Alexandroff has had constructed a compass like that of Weber, in order to appreciate an early hypertrophy of the subcutaneous fat in coxalgia, which he looks upon as a sure sign of the tuberculous nature of the affection.—*Arch. Méd. Belges,* January.

Precocious Hepatic Syphilis with grave icterus and acute yellow atrophy of the liver is discussed in a paper by Dr. Ch. Talamon (*La Médecine Moderne,* February 13th), and the following conclusions are presented: 1. That severe icterus which occurs in the secondary period of syphilis is not a coincidence, but indeed a direct manifestation of syphilitic infection in the same degree as are the roseola and mucous patches with which it coexists. 2. That this severe icterus is a symptomatic expression of an acute diffuse hepatatis, either interstitial or parenchymatous, possibly ending in acute yellow atrophy of the liver. 3. That it is logical to suppose that this acute syphilitic hepatitis has not as a necessary consequence a fatal termination, and that there is consequently reason for admitting lighter and more curable forms. 4. That simple precocious syphilitic icterus is probably but one variety of these curable forms of syphilitic hepatitis. 5. That between these two extreme varieties there exist in all likelihood intermediary forms of medium gravity, as an observation of Senator would tend to prove. 6. That we may consequently bring together under the name precocious hepatic syphilis, by analogy with precocious syphilitic Bright's disease, the various manifestations of secondary syphilis of the liver; the most benign manifestation being represented by simple precocious syphilitic icterus, the most grave by syphilitic icterus with acute yellow atrophy of the liver.

Paroxysmal Tachycardia in a child of eleven years was discussed by the London Clinical Society on the 8th of January. The condition had existed for five years. The palpitation would come on suddenly and cease quite as suddenly after a period of from one to fourteen days, during which the pulse beat would be 240 to 260 per minute. At times there was slight cyanosis; urine scanty; no valvular disease; no lues. Changes in the myocardium were blamed for the affection, which seems to be rare in childhood. In the discussion which followed, the possibility of nutritive disturbance of the heart centre in the medulla was suggested. It was also stated that in many instances, in which during life no heart affection was discoverable, an anatomical lesion of the myocardium would be made out at the autopsy. Disease of the nervous system does not explain paroxysmal tachycardia, since affections of the vagus itself do not give a pulse beat of over 150; and displacement of the abdominal organs likewise fails to explain the condition. As remedial measures, a vesicating plaster over the vagus, a combination of arsenic and bromide of ammonium, valerianate of zinc in beginning dose of two decigrams, and compression of the thorax and abdomen at the time of attack, were all recommended.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, March 27, 1897.

TESTS FOR SUGAR IN THE URINE.

IF one might be pardoned for thus judging of the matter, by the number of very recent recommendations for the discovery of sugar in the urine which have appeared in foreign and domestic literature, Fehling's solution must be thought to have its failings. Its instability and the necessity for frequent renewal of the solution are among the drawbacks to its use.

In quantitative analysis, too, the results are unsatisfactory, especially when the urine contains but little sugar. Rangé has, however, recently indicated in the *Bulletin Médical* a simple method of employing Fehling's solution for this purpose, which is briefly as follows: Drop twenty drops of the solution into a test tube, bring to a boil, and add the urine drop by drop until decolorization takes place. Divide the number one hundred by the number of drops required, and the result obtained indicates in grams and centigrams the proportion of sugar per litre.

It is recommended that after adding two or three drops of urine and having heated the mixture to let it rest awhile, since the yellow or reddish color of the cupric oxide may mask the blue tint of the liquid. The precipitate once deposited, one can judge whether the clear fluid is still colored blue or not. To save time, Dr. Duhomme has recommended the test to be made in six separate tubes at once, adding one drop of urine to the first, two to the second, and so on. If no result is obtained after the boiling and cooling process, six drops are added to each tube, so that No. 1 now contains seven and No. 6 twelve. The drops should be deposited at the bottom of the tube and not permitted to run down the side. Another test in which Fehling's solution is utilized is that advocated by Gerrard in the *American Druggist and Pharmaceutical Record*, xvi., 1895, for the detection of minimal quantities of sugar with the aid of a cyanide-of-potassium solution.

Dr. M. McDonald, writing in *The Lancet* of September 19, 1896, on the detection of small quantities of sugar in the urine, says the most satisfactory test is that of phenyl-hydrazin, which is very sensitive, and this is its chief objection, small isolated yellow crystals making it necessary to apply other tests or to retest after fermentation.

The method he employs is: To 20 c.c. of urine in a test tube add 0.75 gm. phenyl-hydrazin hydrochloride and 1.0 gm. sodium acetate. Put in a water bath at about 90° C. for forty minutes. Allow to cool slowly, and after some hours examine the precipitate under the microscope. If albumin is present in any quantity, it should first be removed, as it sometimes interferes with the formation of the crystals of glucosazone.

A recent writer in the *Medical Chronicle* gives a somewhat modified method: In an ordinary test-tube powdered phenyl-hydrazin is introduced to the depth of half an inch, then powdered acetate of sodium in equal amount, and urine is added to the middle of the tube. Upon boiling the powder dissolves, but it is advised to continue boiling for two minutes. Upon standing a yellowish deposit forms, which is seen under the microscope to consist of beautiful needle-shaped crystals of bright sulphur-yellow color. Brown amorphous globules or yellowish scales are found when sugar is not present. In carrying out Sir William Robert's recent recommendation to filter through animal charcoal in order to remove the normal reducing agents which interfere with delicate tests, McDonald found that the charcoal kept back a large proportion of the sugar, and that washing the charcoal afterward with distilled water and applying Trommer's test gave a good reaction. Three separate formulæ having sulphate of copper as their chief reagent have recently appeared—that of Whitney, which was described in the New York *Medical Journal* of January 25, 1896; that of Schreiber, *Apotheker Zeitung*, x., 1895, 782; and that of Elliot, which was given in the MEDICAL RECORD of January 23, 1897, page 124.

The Schreiber test is really one of salicylate of copper:

Sulphate of copper	2 gm.
Salicylate of sodium	2 gm.
Carbonate of sodium (cryst.)	8 gm.
Distilled water	up to 100 c.c.

Filter.

Five cubic centimetres are added to an equal quantity of urine and heated until a precipitate forms; if the latter is gray or black with the same mirror upon the sides of the test tube, no sugar is present, but if the precipitate and mirror are yellow, it is. It is said that this reagent serves equally for the approximative determination of the quantity of sugar present. Thus, if the five cubic centimetres require two cubic centimetres for the production of the yellowish mirror, the urine contains ten per cent; if two and a half are required, it indicates one per cent.; and if three must be added, one-tenth per cent.

Williamson's "simple method of distinguishing diabetic from non-diabetic blood," published in the MEDICAL RECORD for February 6th, page 196, may be applied to urine examinations as well, and some investigations have been carried out in this direction. It would seem therefore that, arising from these many suggestions, there should be found a reliable and at the same time convenient test for both the presence and proportion of sugar present in any suspected case of diabetes.

THE HEALTH BOARD AND COMPULSORY REPORTS OF TUBERCULOSIS.

The reports of the committees of the New York Academy of Medicine, the Medical Society of the County of New York, and the New York County Medical Association have shown that the medical profession of this city is not yet ready to approve the recent order of the health board regarding compulsory returns for tuberculous cases. To such as read the reports in the present issue it will be evident that we correctly interpreted the opinion of the members of these different bodies when we predicted that the measure would not be indorsed. The academy, with becoming earnestness, views the question of prevention in its broader and more practical aspect. Instead of advising that hospitals for the treatment of indigent tuberculous patients be under the charge of the board, it recommends that they be under the control of the city authorities, the board of charities, to which they properly belong. It is also wisely advised that the enforcement of compulsory notification be delayed, and this, too, by a thoroughly representative committee composed of a chairman and secretary whose authoritative influences no one will question.

The Medical Society of the County of New York is still more emphatic in its protest. In the language of the resolution adopted by an unanimous vote it is declared that "the recent edict of the health department in relation to the compulsory reporting of cases of tuberculosis is unnecessary, inexpedient, and unwise."

It would now appear that the time has come for the health board to rescind the obnoxious regulation, in order that it may, as formerly, work in harmony with the wishes of the profession.

THE MONTREAL MEETING OF THE BRITISH MEDICAL ASSOCIATION.

We have been taken to task gently by an esteemed correspondent for the warning which we uttered recently, against the unbidden attendance of Americans at the meeting of the British Medical Association at Montreal. He seems to think that the warning was anglophobic in its inspiration, and asserts that Americans will be as welcome at Montreal as Canadians or Englishmen would be at any meeting of the American Medical Association.

It is unnecessary to disclaim any national prejudice as a motive for our warning, for there is not a word in it to justify such a charge. But when our friend, who, in expressing his own feelings of friendliness voices, we trust, those of his fellow Canadians, states that all physicians from this country will be welcome, he is not speaking by the book. The notice which we quoted from the *Canada Lancet* appeared in identical form in most if not all of our Canadian exchanges, and was evidently inspired from headquarters and intended as a warning to American physicians to wait for an invitation before coming to the meeting. It will be seen from the letter of Dr. Adami to the Medical Record, published in this issue, that a number of invitations will be sent to prominent members of the profession in the United States, the number being limited only by the necessities of the case. And our Canadian confrères desire it to be distinctly understood that while they would be glad if it were possible to welcome all, they will be forced to restrict their hospitality to such as are bidden.

A FOOL'S COMPLAINT.

The principal speaker at a recent dinner of the Irish Revolutionary Brotherhood, held to commemorate the Irish uprising in 1867, was a man whom the papers call a "civil justice." He took for his theme "Liberty," which he grieved to think was rapidly being throttled in our land. He cried that the liberty of the American citizen was fast diminishing, and that there was an ever-increasing decadence of personal rights. He offered in proof of all this the tyrannical decree which had recently been promulgated, forbidding him to deposit the excrement from his mouth in public places. A civil justice who complains because he cannot void his excretions in public, and thinks that his liberty is thereby curtailed, is as little fitted for the official position he holds as he is for the society of his fellow-men. An asylum is where he belongs.

News of the Week.

Medical School Inspectors.—The one hundred and fifty medical inspectors of schools have been appointed by the board of health and are now under instruction. All but three of the candidates who passed the civil-service examination received appointments in the corps. They will begin their new duties on March 29th.

The Twelfth International Medical Congress.—The chairman of the American national committee writes us that extracts of papers to be read before any of the sections ought to reach the secretary-general before June 1st, in order to be printed in the preliminary volume. The transatlantic steamship companies one and all refuse any reduction of the usual charges. In their replies to the letter of the secretary-general they admit the existence of an agreement which prevents them from lowering their prices. *The Lancet* gives the cost of the railway journey approximately as follows: A circular ticket from London via Paris, Strasburg, Munich, Vienna, Oderburg, and Granica (frontier station for Moscow), and home via Eydtkuhnen (frontier station from St. Petersburg), Königsberg, Berlin, Cologne, Brussels, and Calais to London, available sixty days, first class, £17 5*s.* (about $85); second class, £12 4*s.* 6*d.* (about $60); fifty-six pounds of baggage free to Avricourt on the out journey and from Blandain on the home journey. For the remainder of the journey baggage must be paid for. The tickets for the Russian portion of the journey must be taken at the frontier stations, the cost being as follows: Granica to Moscow, first class, 38 roubles 43 kr.; second class, 24 roubles 68 kr. Moscow to St.

Petersburg, first class, 20 roubles 76 kr.; second class, 12 roubles 21 kr. St. Petersburg to Eydtkuhnen, first class, 17 roubles 90 kr.; second class, 10 roubles 74 kr. No return tickets are issued on the Russian railways. Taking the rouble at 2*s.* 3*d.*, the approximate cost of the railway travelling will thus be: First class, £26 ($128); second class, £18 ($85). The secretary-general holds out some hope of the fares on the Russian lines being considerably reduced. All visitors will be required to be provided with passports. It is hoped that the members of the congress will be received at a court reception by the Czar, and arrangements are being made for fêtes to be held at St. Petersburg after the termination of the meeting at Moscow. The chairman of the American national committee is not authorized to issue certificates of any kind in favor of congressists. He will try to ascertain, however, in which way their movements may be facilitated, and may receive a reply in the second half of April. A special prospectus, containing the final details referring to travelling, lodging, festivities, etc., is promised for a near future.

The Maryland Public Health Association has been formed as the result of the conference of health officers held in Baltimore on February 17th and 18th. This conference was called on account of the prevalence of typhoid fever and diphtheria in that State, and was attended by representatives from every county in the State.

College of Physicians of Philadelphia.—A stated meeting of the College of Physicians of Philadelphia was held on March 3d, the president, Dr. J. M. Da Costa, in the chair. Dr. D. D. Stewart read a paper "Concerning the Blue Line in the Gums in Lead Poisoning," in which he pointed out that this line is dependent upon the combination of the lead salt circulating in the blood with the sulphur contained in the food, forming an insoluble lead sulphide. Drs. S. Weir Mitchell and A. H. Stewart presented a communication entitled "Studies of the Blood in Crotalus Poisoning, with Photographic and other Illustrations." They described the degenerative influence of crotalus venom upon normal blood, and showed that this effect was present in very much smaller degree in the blood of immunized animals. The report, which is not yet complete, represents a continuation of the work begun by Dr. Mitchell some twenty years ago, resumed a few years ago in conjunction with Dr. E. T. Reichert, and again taken up in the sequence of the recent developments of the investigations of Calmette and Fraser. Dr. Charles W. Burr read a paper entitled "The Mimicry of Tumor of the Brain in Bright's Disease," in which he related cases illustrating the fact that nephritis, and especially the uræmic state, may be attended with almost any of the symptoms of tumor of the brain, as well as of other cerebral lesions, such as hemorrhage and vascular obstruction, so that at times the diagnosis is beset with the gravest difficulties. The mere absence of albumin and tube casts from the urine is not always decisive. Dr. John K. Mitchell read a paper entitled "Curious Symptoms from Fracture of Lateral Vertebral Process," relating a case in which the extremity of a lateral process of one of the lumbar vertebræ was broken off, and gave rise to somewhat obscure though rather distressing symptoms, relief from which was afforded only by surgical interference, with detection of the actual condition and removal of the offending irritant.

Obituary Notes.—Dr. Ernest A. Hoffmann died at No. 45 West Twenty-fifth Street, this city, on the 11st inst. Born in Germany in 1832, he came to this country in 1852, and graduated from the medical department of the New York University in 1858. For several years he practised in Poughkeepsie. In 1867 he became a professor in the Medical College for Women in this city.—Dr. Sumner A. Mason, of 128 West One Hundred and Twenty-seventh Street, died on the 12th inst., from congestion of the brain, being found unconscious in his office by his daughter, with whom he lived. He was fifty-eight years of age, a graduate of the University of Pennsylvania of the class of 1868.—Dr. H. Hoffman Baker died at Philadelphia on March 15th. He was graduated from Jefferson Medical College several years ago.—Dr. Manoah S. Long died at Mertztown, Berks County, Pa., on March 16th, of pneumonia, at the age of fifty-six years. He was graduated from the University of Pennsylvania in 1862.—Dr. Arnold H. A. Schott died suddenly at Philadelphia on March 18th, at the age of seventy years. He was born in Wetzlar, Germany, and served as lieutenant in the army, later being appointed as instructor in the military academy at Berlin. He was graduated from Jefferson Medical College in about 1868.—Dr. James A. Fisher died at Reading, Pa., on March 6th, at the age of sixty-five years. He was graduated from the Pennsylvania Medical College in 1854. He was prison physician for three years, and at the time of his death was a member of the school board.—Dr. Peter D. Keyser died of pneumonia at Philadelphia, on March 9th, after a short illness, at the age of sixty-five years. He was graduated in 1852 from Delaware College, receiving the degree of A.B., and subsequently that of A.M. For two years he then occupied himself in the study of chemistry, afterward going to Germany to continue his studies. In 1861 he entered the United States army as captain in the ninety-first regiment of Pennsylvania infantry, United States volunteers, and served with the army of the Potomac in the Chickahominy campaign on the staff of Brig.-Gen. Henry M. Naglee until after the battle of Fair Oaks. On account of ill health and wounds received, he resigned his commission in the army in 1862, and revisited Europe, where he entered the medical department of the University of Munich, and afterward that of Jena, receiving from the latter the degree of M.D., in 1864. He subsequently visited Berlin, Paris, and London, and then returned to the United States, to be appointed acting assistant surgeon in the United States service, being detailed to the Cuyler Hospital at Germantown. In 1864 Dr. Keyser founded the Philadelphia Eye and Ear Hospital, and became its surgeon in charge. He was also surgeon to Wills Eye Hospital and to the medical department of the German Society.

In 1883 he was made professor of ophthalmology in the Medico-Chirurgical College, and for nine years was also the dean of the college. Since 1889 he was a member of the board of health. He was a member of many scientific and social organizations.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C., March 22, 1897. Changes in the medical corps of the United States navy for the week ending March 20, 1897: March 13th.—Assistant Surgeon D. N. Carpenter detached from the United States naval laboratory and department of instruction, Brooklyn, N. Y., and ordered to the *Brooklyn*, March 15th; Assistant Surgeon F. L. Pleadwell detached from United States naval laboratory and department of instruction, Brooklyn, N. Y., and ordered to temporary duty on the *Constellation*, March 15th. March 16th.—Surgeon H. G. Beyer detached from the *Newark*, March 17th, and ordered home to await orders; Assistant Surgeon A. W. Dunbar detached from the *Newark*, March 17th, and ordered to the *Vermont*. March 17th.—Surgeon M. H. Simons detached from torpedo station, Newport, R. I., April 15th, and ordered to the *Columbia*; Surgeon E. Z. Derr detached from the *Columbia*, on being relieved, ordered home, and granted three months' leave; Passed Assistant Surgeon J. M. Moore ordered to the *Alert*, upon the arrival of that vessel at Mare Island, Cal.; Passed Assistant Surgeon L. W. Spratling detached from the *Alert* upon being relieved, ordered home, and granted three months' leave.

The American Medical Association.—The following addresses will be delivered at the meeting in Philadelphia the first week in June: Presidential address, by Dr. Nicholas Senn, of Chicago; address in surgery, Dr. William W. Keen, of Philadelphia; address in medicine, Dr. Austin Flint, of New York; address in State medicine, Dr. John B. Hamilton, of Chicago. The late Dr. Jerome Cochran was elected in Atlanta to deliver the address in State medicine. He was in favor of entrusting to the Marine Hospital services the duties of the proposed department of public health of the central government; Dr. Hamilton opposes this proposition.

An Epidemic of Typhoid Fever has been prevailing among the employees of the Lambertville (N. J.) Rubber Company, thirty-three of the two hundred and fifty hands being compelled to give up their work, and thirteen developing virulent typhoid fever. It is thought that the disease was transmitted through the use of water obtained from a contaminated well.

A Philadelphia Enterprise.—The *Medical and Surgical Reporter* calls attention to a most extraordinary announcement, which appeared in the Philadelphia *Evening Telegraph* of February 15, 1897. The headlines of the article are worth quoting, if only to show the strictly professional character of the advertisement. They read: "Diseases of the Stomach. The Long-Needed Institution for their Treatment will soon be Ready for Service. Wide Field for its Work. Will be Situated at Broad and Brown Streets, with a Distinguished Staff. Boon to the Thousands." Then the writer, prefacing his remarks with the indisputable statement that "the need of a special hospital devoted to the treatment of diseases of the stomach has long existed in this city," enters into details concerning this "boon to the thousands," from which we learn some interesting facts concerning the great enterprise: "The institution will be known as the American Hospital for Diseases of the Stomach, and will be located on the corner of Broad and Brown streets, which offers exceptional facilities for this purpose. The building is a large and commodious one, with an imposing brownstone front. . . . The objects of the hospital will be: 1. To treat by the most modern method those suffering from diseases of the stomach and bowels. 2. To provide comfortable surroundings and proper food for those unfortunately afflicted with cancer, ulcer, appendicitis, and other ailments of the stomach and bowels. 3. To establish a well-equipped laboratory for research work in the line of food adulteration. 4. To establish a school of dietetics, in which free instruction to the public will be given in the hygiene of food adulteration. . . . Physicians of the highest repute and well-known specialists have agreed to devote their time and experience toward the success of the undertaking. The following medical staff will do the work of the institution, some as consultants and others in active duty: Prof. J. M. Da Costa, Prof William Osler, Prof. W. W. Keen, Prof. James Tyson, Dr. John B. Deaver, Dr. D. D. Stewart, Dr. Lewis Brinton, Dr. E. K. Perrine. As this is the only institution of its kind in the country, it is only fitting that the great medical centre of Philadelphia should be the first to take the lead in the matter." And yet the envious call Philadelphia sleepy!

The Hospital for Consumptives of Maryland, which was recently opened in Baltimore, is filling a great want there. St. Joseph's Hospital has also set apart a ward of forty beds for the treatment of pulmonary tuberculosis.

The Health Department of Baltimore has been called upon to look into the condition of a number of bakeries reported to be in a filthy state. Nine hundred and seventy-eight inspections were made last year, resulting in a decided improvement in cleanliness.

Dr. Nansen.—The Norwegian parliament has unanimously resolved to confer upon Dr. Nansen, the Arctic explorer, a professorship of zoölogy at the Christiania University.

Vital Statistics of Philadelphia.—For the week ending March 13th there occurred in the city of Philadelphia 521 deaths, 16 less than during the preceding week and 7 less than during the corresponding week of the previous year. Of the whole number 163 occurred in children under five years of age. The principal individual causes of death were as follows: Pneumonia, 105; pulmonary tuberculosis, 54; heart disease, 24; diphtheria, 21. There were reported during the week 82 cases of scarlet fever, 58 of diphtheria, and 46 of typhoid fever.

The Color Line in Physical Culture.—An instructor in physical culture in Louisville, Ky., resigned a short time ago rather than lecture to colored teachers.

A Parisian Medical Man will, it is said, be invited to deliver one of the general addresses at the Montreal meeting of the British Medical Association, as a compliment to the French Canadian physicians.

Lombroso's Opinion of Zola.—M. Zola is an epileptoid with prehensile foot, precocious wrinkles, gastric crises, anguish and vertigo after intellectual effort, and hystero-epileptic psychosis, or, at least, a paranoiac psychosis.

The Bill for a Department of Public Health was introduced into the fifty-fourth Congress by Senator Gallinger. It provided for the appointment by the President from the medical profession of a secretary of public health, with an annual salary of $8,000, and of an assistant secretary at an annual salary of $5,000. Among the duties of the secretary of public health would be to obtain through all accessible sources weekly reports of the sanitary condition of all ports and other places in the United States; to tabulate statistics of marriage, births (noting those that are illegitimate), stillbirths, with cause thereof and period of utero-gestation, and deaths from all diseases and from violence, accident, suicide, murder, and data concerning the fruit of consanguineous marriages and the transmissibility of insane, alcoholic, syphilitic, nervous, and malignant types of constitution to offspring, and the evils of race miscegenation; to procure information relating to climatic and other conditions affecting health, and especially in reference to the most favorable regions in the United States for the cure or relief of chronic diseases, particularly consumption; to procure information as to the prevalence and ruinous effects upon the body and mind of intemperance and prostitution; to endeavor to ascertain the extent, the origin, and classification of insanity in the several States and Territories of the country; to investigate the state of comfort of the laboring classes in respect to their lodgement, their trades, occupations, the healthfulness of their workshops and the contents of the atmosphere they habitually breathe, and the prevalence of premature degeneration of the nervous and muscular system by the exactions of piecework employment, and to obtain information in regard to the soundness of their food and purity of water supply; to ascertain the ages at which the children of the poor are put to work and its hindrance to their physical development, and their lack of common-school education; to seek information of the hygienic state of public-school buildings, respecting their illumination, ventilation, and presence of noxious elements in the circumambient air; to seek information in regard to the pollution of streams and navigable waters and public and private wells; to attempt to promote the most extended and thorough training of students, in order to fit them for the practice of medicine; whenever an epidemic disease is spreading abroad, or in any country which by commercial or other relation may endanger the health of the inhabitants of the United States, to call a conference of the surgeons-general of the army, navy, and marine-hospital services, and the executive officer or officers of the various State boards of health throughout the country, to consider and advise with them in regard to the best methods to pursue to protect the country against the invasion of any such epidemic disease. The secretary of public health, if a bill similar to this should ever pass Congress, would evidently have no sinecure. It was proposed to appropriate $50,000 to defray the expenses in carrying out the provisions of this act.

Tri-State Medical Societies are becoming very fashionable of late. The latest one to be established comprises, we believe, the State of West Virginia and the western parts of the States of Pennsylvania and Maryland. If this is not the exact combination, we are open to correction. The Tri-State Medical Society of Iowa, Illinois, and Missouri will meet in St. Louis on April 6th, 7th, and 8th. The programme of this meeting contains the names of eight men from States other than those mentioned in the title of the society.

The Mysteries of Medical Casuistry.—Dr. Campbell Black, of Glasgow, has a disagreeable habit of asking questions, and has lately taken to seeking information anent medical advertising. He writes to the *Medical Press* that he has seen in its columns an editorial opinion that the advertising of medical books in lay papers was wrong. Then he continues that he has just read in a morning paper that one of the medical professors of the University of Glasgow delivered a lecture the day before in the lecture room of the Pathological Institute of the Western Infirmary, on "Inflammation," and "that there was a large attendance of the public." "Can you enlighten me," he says, "one ever perplexed as to the mysteries of medical etiquette, how, if the one course be heinous, the other is commendable?"

Pathological Society of Philadelphia.—A stated meeting of the Pathological Society of Philadelphia was held on March 11th. Dr. J. M. Swan exhibited tibias from cases of rachitis and caries of femur, tibia, and fibula. Drs. Joseph McFarland and W. W. Babcock exhibited a large spindle-cell sarcoma of the ovary and also a uterus bicornis. Drs. C. W. Burr and D. J. McCarthy exhibited a primary carcinoma of the pancreas, with secondary invasion of the liver and the brain. The cerebral symptoms were the most conspicuous and led to an incorrect diagnosis of tumor of the cerebellum, while the neoplasm was situated in the prefrontal lobe. Dr. A. C. Abbott exhibited actinomyces fungus. Dr. Alfred Hand, Jr., exhibited an infantile heart displaying a patulous ductus arteriosus. He showed also miliary tuberculosis of lungs, spleen, and intestine. Dr. J. D. Steele demonstrated rupture of the liver and of the spleen, together with hemorrhage into the lung and diminutive aorta and pulmonary artery, associated with hypertrophy of the heart, from a case of violent railway injury.

Clinical Department.

A CASE OF CREOLIN POISONING.

By ALBERT G. ANTHONY, M.D.,

SYRACUSE, N. Y.

The patient, aged five years, was my own child. He had whooping-cough and we were using inhalations of creolin. One night by mistake the nurse gave him a teaspoonful of the creolin, thinking it was cough syrup. In a moment the mistake was known, as the agony of the child was something terrible. His lips and chin were white. I was making a call a short distance from home, and a messenger was hurriedly dispatched for me; and when I arrived, about ten minutes after the accident, the child was comatose, the pupils were very much contracted, the skin was cold, and there was complete muscular relaxation. Breathing was superficial, jerky, and irregular. The pulse was rapid, faint, irregular, and at times very indistinct. I learned that a glass of milk had been given, followed by lime water, and, as the child became unconscious, nothing more was given. The general condition of the patient suggested the use of atropine, and I gave one-one-hundredth grain hypodermatically, followed in thirty minutes by a second dose of one-fiftieth grain. Artificial respiration was kept up in the mean time. Shortly after the second dose of atropine the pupils began to respond and the heart's action improved. Sufficient consciousness was restored in two hours to permit liquids being given by the mouth, and I began the administration of sulphate of magnesium in saturated solution until four drachms of the powder had been given. The improvement continued. Six hours after the ingestion of the poison one ounce of black urine was discharged. The urine deposited a black granular sediment resembling charcoal. No incidents of moment marred the complete recovery, except the unpleasant effects of the supersaturation of the system by atropine and the local corrosive effect of the poison on the lips, mouth, and throat. Two thoughts impressed themselves on my mind, viz., the specific indications for atropine and the value of the sulphates.

MARKED VARIATIONS, FROM TIME TO TIME, IN THE COLOR OF THE IRIDES OF A YOUNG WOMAN.

By J. C. CLEMESHA, M.D.,

BUFFALO, N. Y.

A short time ago, I was consulted by Miss C. on account of deficient vision for distance and discomfort after using the eyes a length of time for near work. Examination into the state of refraction showed myopic astigmatism and suitable glasses were prescribed. During the consultation she volunteered the statement that the color of her eyes varied from time to time, which fact had been noted by her family physician and a number of her friends. The color of the irides varies from black to a bluish-gray through the various shades of brown, brownish-yellow, yellowish-green. Sometimes, she tells me, they resemble the color of a cat's eyes. The young lady is strong and healthy, has suffered from no serious illnesses, though the fact must be noted that her hair, dark at the time, changed to gray at the age of eighteen, and has remained so ever since. Mental emotion seems to be a factor in the causation of these changes.

The Johns Hopkins Hospital has opened a maternity ward.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 18, 1897.

Edward G. Janeway, M.D., President, in the Chair.

Report of Committee on Tuberculosis.—The following was the report of the committee appointed at the January meeting for the consideration of tuberculosis:

"The committee met March 12th, and now presents to the academy as a result of its deliberations the following statements:

"1. In the opinion of this committee the board of health might wisely delay the enforcement of compulsory notification, but should adopt more stringent measures for the care of sputum in factories, workshops, tenement houses, ferryboats, places of public assemblage, and public conveyances.

"2. In the opinion of this committee the establishment and maintenance by the city of a hospital or hospitals, to which indigent tuberculous patients may be admitted, is advisable.

"3. This committee recommends the appointment by the legislature of a commission for the establishment and management of sanatoria in healthy country districts in this State, for the care of the indigent tuberculous patients in the early stages of the disease.

"4. This committee would commend to the State board of health the importance of the careful regulation of the sanitary condition of hotels and sleeping-cars throughout the State.

"E. G. Janeway, M.D.,
"*Chairman.*
"T. Mitchell Prudden, M.D.,
"*Secretary.*"

On motion the report was accepted and adopted.

Experimental and Pathological Observations on the Uræmic Intoxications.—Dr. C. A. Herter read a part of a long paper on uræmic intoxication, based on numerous experimental and pathological observations carried on during several years. He would undertake to show that all of the clinical phenomena classed as uræmia ought to be referred directly or indirectly to a toxic state of the blood, and not primarily to mechanical causes. Further, that the toxæmic theory of uræmia not only involved no restriction on the present use of this term, but, on the contrary, made it desirable to extend its application to some cases in which the clinical conditions were unobtrusive or masked.

The observations were principally of two kinds, experimental and chemical. The experiments on animals consisted chiefly in the injection of the serum of the blood of patients presenting uræmic conditions. Through the kindness of various physicians, particularly those connected with the hospitals, it had been possible for him during the year to obtain blood from twenty-eight uræmic patients, the serum of which he injected into rabbits, in a few instances into dogs and monkeys. Rabbits were not chosen because they were best for this purpose, but because for them a small amount of serum, which alone could usually be obtained, would answer. The injections were made at the rate of ten cubic centimetres per minute. Of the twenty-eight patients, eleven had had repeated convulsive seizures, two puerperal convulsive eclampsia; six were subject to chronic nephritis; the remainder showed such uræmic symptoms as headache, dyspnœa, contracted pupils, etc.

In investigating the influence of urea in the production of uræmia, the first step had been to determine the amount of urea contained in normal blood; next,

to determine the amount present in uræmic states. The urea of normal human blood was 0.02 to 0.05 per cent.; of normal dog's blood, 0.03 to 0.07 per cent. Urea of normal human urine, 2 to 3 per cent. Urea of blood in human nephritis might reach 0.8 per cent. Urea of blood in a nephrectomized dog might reach 0.6 per cent. Fatal quantity of normal human blood serum injected intravenously in rabbits weighing from 1,000 to 2,000 grams, at the rate of 10 c.c. per minute, was 50 to 150 c.c. Fatal quantity of human blood serum from cases of uræmic convulsions, 12 to 30 c.c.

There were two main classes of human uræmia: *A*, urea of blood serum normal, toxicity of blood serum increased. *B*, urea of blood serum increased, toxicity of blood serum increased. The importance of class *A*, in which the urea of the blood serum was normal while the toxicity was increased, was the fact that urea could be positively excluded as the cause of the symptoms. Several cases belonged to this class. In class *B* were thirteen cases. In this group the quantity of serum required to kill the rabbits weighing from one thousand to two thousand grams varied from 12.5 to 47 c.c. The blood serum in this class possessed the highest degree of toxicity, and the amount of urea which it contained was from two to ten times the amount in normal blood. Most cases of uræmia complicated by other diseases showed a marked increase in the amount of urea contained in the serum. The cases related showed also that some cases of chronic nephritis without distinctly uræmic symptoms presented increased toxicity of the blood serum.

The conclusions which Dr. Herter had drawn from experiments with the blood serum in the normal and uræmic states were chiefly as follows: That normal human blood serum was only moderately toxic when injected intravenously; that in some cases of chronic nephritis without distinct uræmic symptoms the toxicity was increased; that in certain cases of uræmic symptoms short of convulsive seizures the toxicity was increased; that in uræmia with convulsive seizures the toxicity was markedly increased; that in many uræmic cases the urea in the blood was markedly increased—not so in some, although there was increase in the toxicity; finally, that the phenomena of uræmia were caused by the toxicity of the blood.

Dr. Herter then directed attention to the nature of the toxic agent or agents in the blood which produced uræmia. The first fact to which he called attention was the effect of heat on the toxicity of serum. In this connection the following statements were made: 1. That the application of moderate heat either greatly reduced or wholly destroyed the toxicity of serum obtained in some cases of uræmia. 2. The application of heat greatly reduced the toxicity of serum obtained from doubly nephrectomized dogs. 3. The application of moderate heat distinctly reduced the toxicity of serum of normal dogs; it would probably have the same effect on normal human serum. 4. In double nephrectomy probably the poison in the blood was merely an accumulation of that which normally existed in the blood in some quantity. Under the addition of this moderate heat the serum changed color, becoming darker.

The author then referred to some theories regarding uræmia. The first mentioned was that which attributed it to urea. As already stated, in certain cases the urea in the blood was not increased, and here this theory could be cast aside. In other cases, however, the blood was not only more toxic, but contained a greater amount of urea. Some experimenters had found urea toxic, others had not. The author's experiments in this connection resulted as follows: That pure urea was toxic in animals when injected intravenously, but only when very large quantities were employed—ten to fifteen times the daily excretion of urea in the animal experimented upon. The symptoms merely fairly constant in dogs—slower, stronger heart action, copious diuresis, contraction of the pupils, irregular fibrillary contraction of the muscles; finally, tonic and clonic spasms and death. In monkeys the symptoms were the same, except that the pupils were dilated instead of contracted. The symptoms occurred much earlier in nephrectomized dogs, because the kidneys were not present to excrete the injected urea.

The author had studied the effects of double nephrectomy in dogs upon the urea in the blood. The urea doubled or trebled in two days, was increased five to ten fold in four days, and the quantity of urea in the muscles, liver, and brain was correspondingly increased. The same effect in greater or less degree followed the checking of the function of the kidneys by cantharides, etc. There was no doubt that the presence of increased urea in the blood depended upon a lesion of the secreting cells of the kidney, the quantity of urea in the blood being in proportion to the renal changes. When the epithelial change was slight there need not necessarily be an increased amount of urea in the blood. These facts were of easy application in acute nephritis in the human being, but the question was more complicated in chronic nephritis. In the latter the excretion of urea might be a little behind, and when an acute nephritis developed uræmic symptoms rapidly manifested themselves. The urea itself had a diuretic effect, which in chronic cases might aid in keeping off acute symptoms. The facts previously alluded to, however, furnished evidence strongly against the view that urea itself was ever the cause of uræmia—the facts being absence of increase of urea in the blood in some cases, and even a diminution of the normal quantity in some instances. The idea, however, that urea did not play an important part in uræmia was not to be taken as indicating that its accumulation in the blood was unimportant. Among its effects which the author had demonstrated experimentally were diarrhœa and vomiting, and these symptoms in chronic nephritis might be due to the accumulation of urea in the blood.

Dr. Herter believed that for practical purposes the consideration of the volume and specific gravity of the urine yielded all the information that could be obtained from the urea in the urine. What we rather required was a clinical estimate of the urea in the blood. He had not time on this occasion to take up the subject of the extractives in the urine, the potassium salts, etc.

The next division of the paper dealt with the pathological differences of the various clinical types of uræmia. Considerable information could be gained from a study of experimental uræmia produced by double nephrectomy in animals. This corresponded to obstructive uræmia in man, and an interesting fact was that the temperature remained normal or subnormal. In both cases vomiting was frequent: there was usually marked muscular prostration from the beginning, occasionally early restlessness: delirium was absent: paralysis had not been noticed. General convulsions were exceptional; consciousness could usually be aroused at any time.

In uræmia of other forms the symptomatology was more complex. In high tension of the pulse, benefit from venesection was attributed to withdrawal of poisons with the blood. Vomiting was sometimes due to gastritis, sometimes to an effort to rid the system of poisons. Convulsive cases were usually attended by slight rise of temperature. The presence of the uræmic poisons did not explain persistent fever, which was present in some clinical cases. There was reason to believe it was due to another factor, namely, infection. It was well known that nephritis was often determined by certain fevers, etc., and it was not astonishing that

this interference with the renal function often precipitated an impending convulsion. In time we should probably know more of the way in which the various infections acted. The author then made some experiments with the use of staphylococci and other bacteria, to determine their influence in cases of uræmia. One might refer to such cases as mixed uræmia. Indeed, to this class belonged by far the largest number of cases, the cases of pure toxæmic uræmia being comparatively rare. Some cases were not easy to classify. This was true of puerperal eclampsia. Before dropping the subject of the influence of infection, the author said there was evidence strongly suggesting in some cases toxic absorption from the intestines. The changes seen in the kidneys of infants suffering from intestinal troubles would go to support this view. In short, we must widen our conception of uræmia as a pathological state. It was not a pathological entity. Speaking generally, any poison which damaged the kidney sufficiently was capable of producing the uræmic state.

Dr. William H. Draper opened the discussion. The observations which the author had made with regard to the toxicity of the human blood serum were very important. Of course, the subject was not new, but important facts had been emphasized and brought out. The toxicity of the blood serum probably varied from hour to hour, and undoubtedly was the explanation of a great many of the discomforts to which human beings were exposed. The paper was also very suggestive, in that it called attention to the analogy between the toxicity of the blood as it was found in many of the infectious diseases and as it was found in the condition which resulted from acute or chronic disease of the kidneys. Probably there was scarcely any symptom of so-called uræmia which could not be presented in the course of any severe infectious disease, such symptoms being caused by the accumulation of excrementitious substances in the blood. He had also been interested by the statement which had received the endorsement of other writers, that uræmia was not a pathological entity. Further, that it was not due to urea, but to a complex condition of the blood. A third point in which he had been particularly interested related to autoinfection from the intestinal canal. Certainly the nervous symptoms in gastro-intestinal troubles in infants were indicative of some autoinfection.

Dr. A. Jacobi would repeat what had been suggested by the paper and the remarks of Dr. Draper, that in infectious diseases we should look for danger arising from the kidneys. It had long been observed in pneumonia in the adult, for instance, that the principal danger was not so much from the pneumonia proper as from an accompanying nephritis. He also referred to those conditions in which the water in the blood was considered as being diminished as instances in which uræmic symptoms were likely to manifest themselves temporarily. On a hot summer day, a person being exposed to the sun, perspiring, without water, a headache and other symptoms developed, which were relieved at once by a glass of cold water. But what Dr. Jacobi wished particularly to lay stress upon was the author's reference to autoinfection from the intestines, and the frequency of nephritis and uræmic symptoms connected with gastro-intestinal affections. Very recently Dr. Osler had denied the existence of fevers arising from autoinfection from the intestines. Dr. Jacobi said there could not be the slightest doubt that nephritis from intestinal autoinfection was very common. It was also almost the rule in various diseases, as diphtheria, pneumonia, etc.

Dr. William H. Thomson looked to such papers as Dr. Herter's as the only practical way to show the relation between the clinical symptoms known as uræmia and the pathological conditions underlying them. He knew of nothing more puzzling than to attempt to trace the relation between such clinical symptoms and the pathological conditions apparent from physical examination. How, for instance, were we to account for dropsy connected with large white kidney, yet less damaged than the atrophic or cirrhotic kidney which was unaccompanied by any dropsy? Other examples were given which showed that uræmic symptoms were not necessarily connected with the condition of the kidney which produced dropsy. There had been albumin in the urine of one of his patients since an attack of nephritis in 1879, low specific gravity, light color, yet he never complained of being sick. On the other hand, not infrequently there was absence of albumin in some patients' urine and yet their uræmic symptoms grew. In connection with the author's remarks upon obstructive uræmia resembling uræmia in animals from which the kidneys had been removed, Dr. Thomson said he had been asked to see a man in consultation who had not passed any urine for eight days, yet there was almost entire absence of symptoms, and the doctor wanted to know why he had not convulsions, etc. Dr. Thomson told him that the man would not show uræmic symptoms, but would die, growing weak, and while there might be twitching there would be no convulsions. It turned out so. The man had had renal colic on the left side thirteen years previously; there was no trouble afterward until lately, when he had had a second attack of renal colic, on the right side, blocking the right kidney. The first organ had been destroyed, the latter recently obstructed. The difference between the two classes of cases was this: that when suppression was preceded by inflammation of the kidney a far more toxic state developed than when suppression occurred without preceding disease.

Dr. Andrew H. Smith said the paper suggested the thought, how much better it would be to do away with the term uræmia and substitute that of toxæmia of renal origin or renal toxæmia. The unexpected results occasionally arising from the administration of drugs could probably be explained by deficient eliminative power of the kidneys. He would never forget the alarming symptoms once caused by a very moderate dose of morphine and it was then found there was disease of the kidneys. Any trifling disturbance of the gastric functions would sometimes lead to very unpleasant results when there was disease of the kidneys. The necessity of making periodical examinations of the urine of all persons under his care should be impressed upon the family physician, in order that he might not be taken by surprise.

Report of Commitee on the Subject of the Health Department in the Charter of the Greater New York.—Dr. P. Albert Morrow read the report. The questions presented in Dr. Stephen Smith's paper had been carefully considered. The powers of the board of health were those which had been conferred by law and had been in operation for thirty years. These powers, which might seem extraordinary, had been tolerated in the past only because the health department had been chary in their use, reserving their exercise for times of emergency. The committee did not recommend a change in the charter in this regard, believing that the conservative influences which had prevailed in the past would continue, and persuaded that if at any time there should be any unwarranted exercise of such powers, a reaction would take place which would bring about restrictive legislation. In the present advanced state of the charter, the committee had thought it advisable to limit its suggestions to that provision which discriminated against physicians in the matter of the presidency of the board of health. Therefore the committee offered the following:

"*Resolved*, That in the composition of the board of

health of the Greater New York there should be three commissioners appointed by the mayor, two of whom should be practising physicians of not less than ten years' standing at the date of their appointment.

"*Resolved*, That there should be a third commissioner. That the third commissioner should be a reputable citizen of the Greater New York, qualified by education and experience for the duties of this office.

"*Resolved*, That the health officer of the port should be ex officio a member of the board of health, and that the president of the board of police should be ex officio a member.

"*Resolved*, That one of the three health commissioners should be designated president of the board by the mayor in making the appointments.

"*Resolved*, That we should abolish the office of coroner and adopt the system in Massachusetts, modified to suit the exigencies existing in New York."

On motion the report was received.

Dr. A. Jacobi said he fully agreed with the propositions made by the committee. There was one thing, however, which had not been mentioned. Dr. Jacobi then read the second of the two following sections, Dr. Piffard reading the first one, or 1,248, subsequently.

"Affidavit may be required.

"Sec. 1,248. The department of health may require any physician to subscribe, not less than three hours after service of a demand thereof upon him, an affidavit, stating therein whether he has or has not any patient, who, in his opinion, shall then be sick of any pestilential, contagious, or infectious disease, and if he has any such patient, to state in such affidavit his or her name and the house or place in said city where he or she shall then be and the nature or name of such disease, to the best of his knowledge and belief.

"Penalty for failing to report.

"Sec. 1,249. Every practising physician who shall refuse or neglect to perform the duties enjoined on him by the foregoing section shall be considered guilty of a misdemeanor, and shall also forfeit for each offence the sum of $250, to be sued for and recovered by the health department. It shall be the duty of each visiting, hospital, and consulting physician, to make an immediate report to the department of health of the name of every practising physician by whom he shall have reason to believe the provisions of said section have been violated; and if such physician shall neglect or refuse to perform his duty, the department shall order him to be suspended from any office he may hold, and he shall, moreover, be liable to such further penalty and to such prosecution for his violation of this law and of his duty as the board of health shall determine."

Dr. Jacobi said this made of physicians spies. It was undignified, unworthy, and dangerous, and certainly ought to be stricken out. Moreover, it was unconstitutional. By law physicians were certainly compelled to report a felony, but by the section physicians were required to report a misdemeanor, which was not in accord with the constitution.

Dr. Piffard read the first section and also entered a strong protest against these sections appearing in the charter.

The president, Dr. Janeway, said this had been the law for about eight years, and had simply been adopted from the present regulations of the board of health into the charter of the Greater New York. He did not know just how it had come to be inserted, but he thought it was from failure on the part of some physician some eight years ago to report a case of typhus fever or cholera. The law might look more aggressive than it was, for he knew of no instance in which it had been abused or enforced.

Dr. Jacobi remarked that if the law was a dead letter it had better be stricken out. If it should be enacted into the new charter, it might become very dangerous.

Dr. Piffard moved to strike out the sections read. There were, he said, some other things in this proposed charter which ought to be stricken out or changed. For instance, sanitary inspectors were given the power to arrest. Further, a citizen on going to a judge and making complaint, could require the judge to order arrest. It was not stated that the judge may but that he shall issue the order.

Dr. Charles E. Quimby thought the very fact that these things which had been said to constitute the law for thirty years was sufficient reason why this charter should now be reconsidered and revised, so as to bring it more in accord with modern knowledge of pestilential diseases, etc. He did not wish to question the actions of the board of health, but he did question the propriety of trusting too much to the wisdom of future members of the board. He thought the time had come in sanitary administration when some restriction should be placed upon the absolute power now given health boards in defining what diseases should be placed under their entire control. They were given power to take charge of all hospitals for pestilential, contagious, and infectious diseases, and physicians might look forward to the time when they would gather up patients with venereal and most other diseases and conduct them to hospitals under their exclusive charge. Without any disrespect to the medical profession, he would say that he thought no man ought to have such a temptation thrown before him. However, he had taken some pains to ascertain the chances of modifying the present charter before its adoption, and had learned that it would be adopted practically as it stood, and that any alterations desired by the medical profession would have to be made subsequently.

Dr. Jacobi moved that the report be laid on the table for the present. It could be taken up at any meeting when there was more time for its discussion. The motion was carried.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, March 15, 1897.

Joseph E. Janvrin, M.D., President, in the Chair.

Balsam of Peru and Castor Oil as a Surgical Dressing; a Study of Twenty-nine Thousand Cases.—Dr. A. E. Gallant read the first paper. It was intended to prove the value of castor oil and balsam of Peru as a surgical dressing which prevented retention and favored drainage and healing. The paper was based on statistics in Dr. Van Arsdale's clinic at the Good Samaritan and Eastern dispensaries, where, out of a total of sixty-five thousand surgical cases the past nine years, the dressing mentioned was used in twenty-nine thousand. A recent editorial by Dr. Pilcher and Dr. Dennis' "Surgery" were quoted to show the important relation existing between retention of fluids and solids in wounds and their infection by bacteria, sepsis, and want of union. The present paper was a continuation of observations recorded by Dr. Van Arsdale a few years ago, when he brought the method of dressing wounds by balsam of Peru and castor oil to the notice of the profession. The accumulation of serum and pus in wounds which could not escape they denominated retention. It was frequently brought about by dry dressings, dry powders, and ointments, which for a few hours absorbed a certain amount of moisture, then became dry, and shut off the discharges until the dressing was changed. In the treatment of fresh wounds

some means must be provided for the escape of blood first and of serum later. To any means by which was afforded exit of blood, serum, or pus, the term drainage was applied. Given a wound with blood clot, closure of the gap, bacteria, and serum as a pabulum, we had all the conditions for suppuration with its local and systemic manifestations. To prevent this we must provide for the rapid absorption of blood, of serum, later of pus, thus deprive the bacteria of their natural food, and render the soil unfit for their development. The dressing which accomplished these purposes best in the experience of Dr. Van Arsdale and of the author was castor oil with from five to six per cent. of balsam of Peru. The balsam oil was spread on gauze, several thicknesses being placed over the wound and covered with oiled silk, oiled muslin, or rubber, retained in place by a bandage or adhesive plaster. In special cases the wound could be powdered previously with iodoform or other agent. Balsam of Peru was too irritating when applied much stronger. It was believed to exert a mild antiseptic action, but the dressing was applied chiefly for its absorbent properties.

Uses: 1. As long as there was any secretion the dressing prevented union or closure of the gap where incision was made, and thus prevented the accumulation of blood or serum in the depth of the wound. 2. Dry gauze would not take up moisture as readily as when previously moistened. 3. The sponge-like action was continuous, and no accumulation could take place. 4. The oily mixture separated the fibres of the gauze, and the secretions were drawn into the interstices. It was, therefore, important to apply a relatively large quantity of gauze. 5. Immediate removal of secretions from the depth of abscesses facilitated rapid contraction of the cavity and aided healing from the bottom.

Neither the oil nor the balsam required to be sterilized. Abscess cavities were never packed, as it would interfere with their contraction. Regarding results, he found that during the nine years in the two dispensaries there had been treated 69,364 new patients, with 154,529 consultations, or an average of two and one-fourth consultations for each patient. Of this number 29,000 had been treated with the balsam-oil, or a little over one-third of the total number of surgical cases. The author classified these cases under burns and scalds, bullet wounds, abscesses, suppurating lymphatic glands, boils, buboes, varicose ulcers, chancres, etc. In burns the blebs were opened; if suppuration had taken place the skin was cut away, the raw surface dusted with powdered bismuth subiodide, and the balsam-oil dressing placed over it. Pain subsided, suppuration and fever disappeared, the reformation of epithelium was remarkably rapid, the cicatrix was soft and pliable. Animal and insect bites were never cauterized; the dressing brought about rapid union. Abscesses as large as an orange of lymphatic glands in children would contract down to almost nothing within three days after they were opened, a drain was introduced and cut off level with the skin, plenty of gauze containing the balsam oil applied, and over this rubber tissue. They considered it important to excite hemorrhage in the least degree possible, as it would open up new channels for septic absorption. Therefore they did not scrape or even irrigate abscess cavities after evacuating them, but simply introduced the drainage tube and applied the balsam-oil dressing. When this was renewed after about three days, it was found to have absorbed all of the discharges, while the cavity was contracted until nothing remained except the space occupied by the drainage tube and the line of incision. It was surprising to see bullet wounds heal so rapidly under the dressing without further measures, the explanation being that all of the discharges were immediately absorbed, leaving no pabulum for the multiplication of bacteria. Certain sores, as varicose ulcers of the leg, tuberculous ulcers, etc., were treated by a more or less modified method. In his hospital work Dr. Van Arsdale had used sterilized oil without balsam for skin grafting, with excellent results.

Having analyzed the numerous cases in which they had used the dressing of balsam of Peru and castor oil, the author summed up its advantages partly as follows: It afforded continuous drainage or sponge-like absorption to the point of saturation, so that the ulcer, abscess, or wound was kept clean and dry, yet soft and moist on the exterior. Retention could not take place; there was no scabbing, no redness, no eczema, no adhesion of the dressing; epithelial growth went on rapidly; there was absence of irritation, of pain, of fever, of infection. The dressing need not be renewed oftener than two, possibly three times a week. Under this treatment irrigation, disinfection, or scraping of abscesses was worse than useless. Dr. Gallant himself applied the balsam-oil dressing in aseptic operative wounds, as in removal of cancer of the breast, with most satisfactory results.

The Origin of the Balsam-Oil Dressing.—Dr. W. W. Van Arsdale, being requested to open the discussion, said they had been driven to the use of the dressing named through necessity rather than through forethought. He had been trained in the aseptic and antiseptic schools, and it was not from choice that he had treated the first cases in the manner described in the paper. It was simply because in the dispensary it was impossible to carry out the details of antiseptic or even aseptic treatment. In his class alone there were sometimes as many as one hundred patients a day who required surgical attention within a period allowing not more than two or three minutes for each patient. Recollecting a case of ulcer once treated by all known methods, without success in bringing about healing, he had resorted to olive oil containing a little balsam of Peru, with speedy success. But olive oil would dissolve only one-half or one per cent. of balsam of Peru, and, speaking to the apothecary about it, they had hit on castor oil, which would dissolve as much as was desired. The paper had described this method in detail, and he could corroborate all that Dr. Gallant had stated. While they were driven to the use of this dressing by necessity, yet they had soon become alive to its advantages and had found the indications for its use steadily widening. But he feared that if he said much more upon the subject it would be inferred that he was biassed. He would, therefore, proceed to state one seeming objection, namely, that the dressing which so thoroughly absorbed all of the discharges took on some odor. While this in no wise interfered with the healing of the wound, yet it was more or less disagreeable. Perhaps something would be discovered to add to the dressing which would do away with this feature. Regarding the use of the dressing in primary wounds, personally he did not employ it in such operations as herniotomy or removal of the breast when the edges of the wound could be brought together, because it hardly seemed necessary as a means to the primary union which was sought. But wherever drainage had to be substituted for asepsis, he could most warmly recommend the dressing. In times of war it would be of special benefit, and ought, he thought, to take the place of the iodoform gauze which every soldier in the German army had to carry. The latter was calculated to shut in secretion and favor sepsis, especially if there were infection, as there was likely to be. The balsam-oil dressing would keep the wound dry and yet moist.

Dr. Fred H. Wiggin recalled some experience when hospital interne under Dr. James R. Wood, in 1878, when little was known about antisepsis. Dr.

Wood was accustomed to leaving wounds open and painting them with balsam of Peru. Unaware of Dr. Van Arsdale's practice, Dr. Wiggin had since made use of balsam of Peru in cases of granulating wounds and ulcers, and had found that it stimulated them to healing and prevented drying of secretions.

Dr. Von Donhoff stated that the principle of asepsis as distinguished from antisepsis was seen every day. A good illustration was the sight of a dog freeing itself of the dressing which with good intention had been placed on its injured limb, and keeping it open by licking it. He would not forget the first impressive lesson taught him by one of the lower animals. A horse had injured its breast; he sewed back the loose mass of flesh and carefully bound up the whole chest, and the horse just as carefully ripped off all the dressing and the sutured mass of flesh as well. Healing went on rapidly, without infection, which probably would have taken place with suppuration had the dressing remained. The only source of healing of wounds was that physiological *vis a tergo* which came from within, unimpeded by external occlusion.

Dr. Gallant said, in the course of some closing remarks, that Dr. Van Arsdale had not used the balsam-oil dressing on primary wounds as often as he had himself, and seemed not to have the same degree of faith in it, or considered it unnecessary. Dr. Gallant, however, believed it was of advantage, doing no harm, insuring absorption of all secretions, preventing possible development of germs, and promoting primary union. In reply to Dr. Wiggin, he said the balsam of Peru was not the important ingredient, but rather the oil; and no doubt something else could be found to take the place of the balsam as a means to keep the oil sweet and to impart a stimulating effect when that was indicated.

Results of Chemical Electrolysis versus Divulsion or Cutting in the Treatment of Urethral Stricture.—Dr. Robert Newman read the paper (see p. 443).

Dr. F. Schavoir, of Stamford, said that if he were asked which department of electro-therapeutics was best, he would say electrolysis of strictures as devised and practised by Dr. Newman. In the treatment of endometritis, uterine hemorrhage, fibroids, etc., there were other measures which could replace electricity, but in urethral stricture all other methods were unsatisfactory. Why was Dr. Newman's method not more generally practised? He could think of but one objection, namely, that a good deal of study was required to understand the principles involved—physiological, electrical, mechanical, and chemical. If doctors would give the treatment a fair trial, they would become as enthusiastic as Dr. Newman. Why was not the whole lining of the urethra dissolved equally with that of the stricture tissue? He thought the explanation probably was the difference in blood supply. An objection to Fort's instrument and another one presented was that only a part of the circumference of the urethra was touched by them at the strictured portion, and, if the stricture tissue were in one side only, it would not be acted upon.

Dr. Samuel G. Tracey said there were many genito-urinary surgeons who feared electrolysis in the treatment of stricture, and he thought it was due to a want of appreciation of the value of the electro-chemical change which took place in the tissues under the negative pole of the galvanic current. Surgical measures even resulted fatally occasionally, and it was far preferable to resort to such a simple measure as electrolysis, which could be applied without danger, injury, pain, or interference with business. Further, the stricture would not return. Electro-chemical absorption took place, produced by a constant current, negative pole, small amount of amperage. If one carried the amperage up to thirty or forty milliampères, there would be cauterization or destruction of tissue. Three to five milliampères were enough. His personal experience led him to believe that the majority of strictures could thus be cured. As Dr. Newman had pointed out, the action of Fort's method was more by tearing than by electrolysis.

Dr. Von Donhoff said that when he had listened to the reading of a paper by Dr. Newman some years ago, he had propounded some questions which still remained unanswered. It was impossible for anybody to answer them. The cure of stricture meant getting rid of the deposit which caused it. Electricity in mild current simply acted as a mild stimulant. He had seen electrolysis used succesfully apparently, but a series of graduated sounds could have been used just as successfully. Dr. Newman, however, claimed that the stricture was cured and did not return. This must mean a return of the canal to its former natural state, which the speaker denied was a possibility.

Dr. Newman closed. The last speaker had commenced with a conundrum, which he himself had admitted nobody could answer. The question, however, whether stricture was cured by electrolysis was answered in the affirmative by statistics of cases with non-recurrence, and one reported case in which autopsy subsequently showed absence of stricture where one had existed prior to treatment by electrolysis. When patients had returned to him it was not for recurrence, but for stricture in another portion of the urethra.

Compulsory Reporting of Cases of Pulmonary Tuberculosis.—This was the special subject for discussion, and representatives of the city health department had been invited to be present.

Dr. George B. Fowler, health commissioner, was first invited to speak, and stated the successive steps taken by the board of health looking to the control of pulmonary tuberculosis. He thought the last step, requiring the reporting of cases of pulmonary tuberculosis, had been misunderstood by many members of the profession, and this fact seemed apparent from the announcement on the card, "Compulsory Inspection of Cases of Tuberculosis." There was to be no compulsory inspection. Inspection would be made if it were requested by the physician reporting the case. A conservative estimate, from the number of reported cases and deaths from tuberculosis, placed the number of patients in the city at twenty thousand, not to mention many unrecognized incipient or obscure cases. The startling prevalence and fatality of tuberculosis was evident from recent European statistics, showing that one-third of all deaths in the German empire were from this disease, and in Vienna nearly one-half of the deaths between the ages of fifteen and sixty were from tuberculosis. Dr. Fowler impressed the fact that the board had not declared tuberculosis contagious, as the remarks of one speaker would indicate. The board had declared it to be among the infectious and communicable diseases, dangerous to the public health.

Dr. J. Blake White thought we were indebted to the commissioner of health for coming and making this explanation. But there was high authority against the positive statement that tuberculosis was infectious and communicable. He quoted the late Benjamin Richardson, the observations of gentlemen in Philadelphia—Cohen, Da Costa, Tyson, etc. These gentlemen, of widest experience in hospitals where tuberculosis existed, had seen no more cases among nurses in such hospitals than in the general population. Dr. Da Costa had known only one out of about one hundred and fifty house physicians to have tuberculosis, and in that instance the disease was not present for five years after he had left the hospital.

Dr. Louis Fischer said the resolutions adopted by the West Side German Dispensary, which had given

rise to this discussion, had been passed on account of the injustice done one of their staff and a patient by one of the inspectors of the health department. Dr. Fischer held that the part taken by the tubercle bacillus in tuberculosis was not clear. It was claimed that infection could be proven by inoculating lower animals. It was true that something more or less similar to what was seen in man could thus be produced by inoculation of animals, but there was a difference, just as there was a difference in similar experiments in diphtheria. We knew that Leaming, Da Costa, and other eminent authorities did not believe that the bacillus tuberculosis was the prime factor in the disease. The statistics based on reported cases were not reliable. He knew of doctors who never even reported cases of diphtheria. How, then, could it be expected that they would report all cases of tuberculosis? He did not believe the inspector of the health department could do any more than the family physician to prevent the spread of infection by the latter's patients. He would like to have the subject referred to the committee on hospitals.

Dr. Noll, a member of the committee on hospitals, objected because their committee already had too much to do. Later, on motion of Dr. Manley, the subject was referred to a committee of three, to confer with a similar committee from the Academy of Medicine and the County Medical Society. The president appointed Drs. Manley, S. B. W. McLeod, and J. Blake White.

Report of Committee on Hospitals, etc.—Dr. Noll read the report at the request of Dr. Stewart. The report contained several recommendations, which were adopted: 1. In view of the fact that some doctors had called on the mayor, asking him not to appoint a physician to fill the vacancy in the charities commission, a resolution was adopted by the association, requesting the mayor to appoint a physician. The resolution called for a committee of three to wait on the mayor, the president to be one; and later the president appointed as the other members Drs. Harrison and Stewart. 2. The second resolution called for the appointment of a committee to confer with a committee from the County Society, with regard to the medical charity abuse. The County Society committee believed the Charity Organization Society would act in this matter, especiallly if the County Association also requested it. Dr. Noll said this was not ideal, but it was probably the best that could be done under the circumstances. Dr. W. Washburn, who was connected with the Charity Organization Society and also a member of the County Society committee, spoke on the question. The president appointed on this committee Drs. Newman, Nott, and Stewart. 3. It was suggested that a committee be appointed to visit J. P. Morgan, to show that the gift for the great obstetric building planned was unnecessary and harmful in influence. The president appointed on this committee Drs. McGillicuddy, Berg, and Beaman Douglass. A fourth suggestion, relating to the remission of dues since 1892, was not adopted, but a motion was passed calling for the number of physicians in arrears.

Diphtheria.—From the look of the throat alone, there cannot be made in many cases a diagnosis between diphtheria and the effects of vesicants and escharotics; the condition which led to the pellicular inflammation must be known. Though of course it is recognized that there are many cases of ordinary follicular tonsillitis, "yet the distinction between the non-contagious affection and true diphtheria can seldom be drawn in a given patient, and therefore in practice it is wise to consider the disease to be in all cases probably, or at least possibly, diphtheritic."—Allbutt, "*System of Medicine.*"

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 22, 1897.

Robert A. Murray, M.D., Vice-President, in the Chair.

Serum Diagnosis of Typhoid Fever.—Dr. C. A. Elsberg read the first paper of the evening. The serum diagnosis of typhoid fever, or Widal's reaction, was demonstrated by microscopic slides and by test-tube specimens. Under the first microscope was a bouillon culture of the typhoid bacilli, under the second Widal's reaction in serum, and under the third the same reaction from dried blood.

A study of the human blood showed that it contained under normal and pathological conditions substances which protected the organism against invasion by micro-organisms. These substances were four, called alexins, antitoxins, bacterilitic substances, and glutein. Having mentioned these substances and the difficulty of diagnosticating typhoid fever by the typhoid bacillus, because of its close resemblance to the colon bacillus, the author passed to the consideration of Widal's method, which he had found very reliable and also very useful in diagnosis under certain circumstances. His observations were based mainly on dried blood, serum having been used in a small proportion of the cases. The reaction consisted in a clumping of the typhoid bacilli when placed in the serum of a patient who had typhoid or had recently recovered. The same reaction took place in dried blood diluted with a proper amount of water. In his own test experiments the serum and the dried blood had been of like value.

The clinical basis of the paper was the examination of the blood or serum of 410 patients—262 of typhoid fever, 148 of the various diseases seen in a general hospital. In only one of the cases without typhoid was the reaction present. The patient not being very intelligent, it was possible she had had typhoid a month previously, of which she could give no distinct account. Of the typhoid cases the reaction was present the first week of the disease in only eight per cent., but in eighty-six per cent. it was present within two weeks. In only fourteen per cent. was its appearance delayed until after the second week, by which time, of course, the clinical diagnosis could certainly be made, unless the course of the disease was quite obscure. The method was of chief value in cases in which the diagnosis remained in doubt after the first week. While the presence of the reaction was almost positive of typhoid fever, its absence did not necessarily exclude that disease. The examination might be made too early in the disease, or at an interval when the reaction was absent, while next day it might be present. In three of the cases reported there was recurrence of the typhoid, and it was only after the recurrence that the reaction was distinctly present. This would point to a relation between the agglutination and immunization. The reaction lasted several weeks after recovery from typhoid, but he had found it in no instance after six months. In one it had disappeared after the eighth day. The reaction was additional proof that the Eberth bacillus was specific of typhoid fever.

Dr. N. E. Brill, in whose service at Mt. Sinai Hospital most of the author's observations had been made, confirmed the statements made in the paper, and said the epidemic among the nurses in the training-school had afforded them unusual opportunities for daily examinations of the blood throughout the course of the typhoid in twenty cases or more. Dr. Brill thought the presence of the Widal reaction furnished immediate proof that the case was one of typhoid. To the trained examiner the reaction was perfectly character-

istic, but it might be mistaken by the inexperienced. He thought that in the few cases reported by some gentlemen in the city of its presence in other diseases might be accounted for by a recent overlooked attack of typhoid. The three cases of recurrent typhoid mentioned in the paper were very interesting, as they would seem to show that so long as the immunization was too incomplete to prevent recurrence the reaction was absent, but after the recurrence immunization became complete and the agglutination was then found.

Dr. W. H. Park thought some anomalous cases might be accounted for on the supposition that there was slight infection by typhoid bacteria, and the reaction was found, but the characteristic symptoms of the disease were not present. Again, in a case at Bellevue a year ago, in which the reaction was striking, there had not been typhoid for a year, but the man had abscess of the liver. In this case the explanation was probably that the typhoid bacilli had remained in the liver abscess. In a few cases, however, this explanation of a positive reaction in the absence of typhoid did not seem clearly to hold. Dr. Park pointed out some advantages of the serum over the dried-blood test, although the latter was usually very reliable. In a case at Roosevelt, absence of the reaction under the serum test led to the exclusion of typhoid, although the entire house staff held to the typhoid diagnosis based on clinical symptoms. Autopsy showed absence of typhoid and presence of tuberculous meningitis. Reaction with a large dilution pointed almost positively to typhoid. At the health department the reaction was present about the sixth day, which in hospital cases would point apparently to the eighth or ninth day. In some instances it was absent until the third week.

Dr. Elsberg agreed with Dr. Park, that when reaction was present unusually long after an attack of typhoid, it might be due to some local abscess or inflammation in which the typhoid bacilli found a lodging-place. He had seen it in a case of periostitis, but had not an opportunity to examine for typhoid bacilli at the site of this disease.

The Mechanical and Operative Treatment of Clubfoot.—Dr. A. M. Phelps read a few notes and presented a number of patients, casts, and photographs, bearing on the mechanical and operative treatment of clubfoot. Authors were now pretty well agreed that heredity had much to do with clubfoot. He was inclined to think that some form of trauma in the uterus played an important part, more particularly forced position, as when amniotic fluid was scarce. Some of his examples of clubfoot showed a position resembling the shape of the uterus. There was no reason to think that either clubfoot or harelip depended upon maternal impressions. The paper of the evening dealt principally with different forms of varus. Mechanical treatment alone was sufficient if begun at birth or not later than the third month. The foot should be twisted into correction, and finally into overcorrection with the hand, and held in that position until the next day or the next dressing by strips of adhesive plaster passing from the plantar surface outward and up on the ankle and leg, these to be supported by roller bandage. Plaster could not be used at this time. In cases seen after the third month, the deltoid ligament or other contracted parts should be divided, and the necessary force used to bring the foot into a position of overcorrection. It was seldom necessary to divide bone, but in one case shown he had found it necessary after his incisions to use a force of fifteen hundred pounds to twist the foot into a position of overcorrection. It was absolutely necessary to retain the foot in the corrected position, otherwise the case would not be cured. In his experience relapses never occurred, except when the patient or parents neglected to return or to carry out the treatment. This number was less than ten per cent. Up to three months ago Dr. Phelps had operated in five hundred cases, and had never had a death. The mortality under older methods was due to bone operations. It was very seldom that division of bone was necessary. He presented a young man, who when a child had been operated upon by the elder Mott, and later by the younger Mott. The foot was in very bad shape when he saw the man, but to-day was practically straight and the patient was walking about.

Dr. L. A. Sayre was requested to open the discussion. He said it would be difficult for him to express his full pleasure on hearing this exposition of the correct treatment of clubfoot. There was nothing to be criticised. If the advice given were generally followed, there would be much less barbarism practised in the treatment of clubfoot.

Dr. Virgil P. Gibney also fully agreed with Dr. Phelps in his exposition of the treatment of clubfoot. He aimed always to get the foot straight. If it could be done by the nurse's hand, that was the method employed. If plaster was necessary, it was used. In advanced or neglected cases he resorted to operative treatment. Almost anybody could get the foot straight by cutting it, but there were few, it seemed, who knew how to keep it straight. Yet that was positively necessary, and was a point which might be more strongly emphasized.

Dr. Kiliani made some remarks in the line of endorsement of the paper, and mentioned the fact that Volkmann, under whom he had studied, had later given up extirpation of the astragalus on account of its dire results, and adopted the method of Phelps as soon as a knowledge of it reached Europe. Dr. Kiliani also dwelt upon the fact that whenever an operation was done it was only the beginning of treatment. The correction must be maintained. Some European surgeons made correction on the instalment plan, but, whether it was done at one time or by degrees, it must be carried out until there was no tendency to relapse.

Dr. Reginald H. Sayre remarked that in many cases it was absolutely impossible to make correction after incision without the use of very great force, and in Dr. Phelps' severe cases presented this evening this must have been the secret of success. Old cases had facets worn into the bones in the false position, and the corrected position must be maintained until new facets formed and there was no tendency to relapse.

Dr. C. Dixon Jones said he had employed only the method described by Dr. Phelps, and had found it sufficient to overcome the deformity.

Dr. Phelps, in closing, said there was no such thing as relapsing clubfoot. Relapse meant failure to carry the treatment to the point of cure. Overcorrect the false position and the weight of the body would itself tend to prevent relapse. Before treatment its tendency was to exaggerate the existing valgus, but supercorrect and it would drive the foot in the opposite direction until it had become solidified in the position the surgeon desired.

Report of the Committee on Hygiene.—Discussion on this report was announced for the present meeting. Dr. Egbert Le Fevre requested that it be read. The secretary, Dr. Avery, read as follows: "Realizing the need of proper measures to prevent the spread of pulmonary tuberculosis, and regarding it an essential preliminary that all physicians be impressed with the importance of making an early diagnosis of the same by a microscopic examination of the sputum, we earnestly recommend that physicians avail themselves of the offer of the bacteriological department of the board of health to make such examinations. We approve of the compulsory reporting of cases of pulmonary tuberculosis if the inspectors are forbidden to visit or to have any communication with the patients

without the consent of the attending physician, believing that the attending physician is capable of giving all the necessary instructions."

Dr. Le Fevre, who as a member of the committee on hygiene had signed this report, said it was drawn up in order that the matter might be placed in some form for action by the society. Personally he had not changed his views much since he had first expressed them upon the action of the health board in requiring compulsory reporting of cases of pulmonary tuberculosis. He was opposed to it. It was a different matter from notification of cases of scarlet fever, diphtheria, and other infectious or contagious diseases which ran a short course. When we reported a case of tuberculosis it was practically for life.

Another point: the board of health must necessarily have large powers, but it ought to be hedged about to some extent in the interests of the patient. They had been told that the proposed new charter was only a continuation of the present charter in most regards. That might be, but was it desirable to renew certain regulations which had fallen into oblivion, yet which, if enforced, might prove dangerous? If the board decided to place tuberculosis among the infectious diseases which had to be reported, it reclassified that disease. The board would have exclusive charge of hospitals for the treatment of such cases. Indeed, if the sanitary code of the present city should become that of the greater city, as provided in the wording of the charter, the health board would be given practically the treatment of all infectious diseases, and it had only to declare a disease infectious in order to take charge of it. Without criticising the present board, which he thought had been very moderate, this was dangerous power. Although he had signed the report for the sake of bringing the matter before the society, he hoped it would not be adopted.

At this point several motions were made, all looking to the rejection of the report and in opposition to the compulsory reporting of cases of tuberculosis, but, as they were not in accord with parliamentary law, Dr. Piffard moved, after the report had been accepted, to adopt it, and said he would vote against it. The report was rejected.

Resolution Adopted Opposing Compulsory Reporting of Tuberculosis.—Dr. A. Y. Reid said he thought the society ought to express in some positive way its disapproval of compulsory notification of cases of tuberculosis. It was unjust to the patient and to the physician. He offered a resolution to that effect, but withdrew it in favor of one read by Dr. Charles E. Quimby, the wording of which he preferred:

"*Resolved*, That in the judgment of this society the recent edict of the health department in relation to the compulsory reporting of cases of tuberculosis is unnecessary, inexpedient, and unwise."

The motion was carried, no voice in the negative being heard.

Epulis. Resection of the alveolar margin is the only logical treatment. Simple extirpation of the alveolar portion of the tumor is to be condemned.—Dr. Edouard Friteau.

Litholapaxy.—A glance at the column of results will show that in proportion as I abandoned lithotomy in my practice in favor of litholapaxy, and as I gained experience of this latter operation, my results improved; and the fact that my last sixteen litholapaxies for calculi of from two up to six and one-eighth ounces were one and all successful show what splendid results we may obtain from Bigelow's operation.—P. J. Freyer, *British Medical Journal*, November 7, 1896.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MEDICAL DEFENCE — LONDON UNIVERSITY — ANNUAL MEETING OF MEDICO-CHIRURGICAL—SURGICAL PHYSIOLOGY OF THE FOOT—CASES EXHIBITED AT THE CLINICAL SOCIETY—A FORTUNE FOR UNIVERSITY COLLEGE HOSPITAL—MIDWIVES BILL—THE LATE SURGEON FYFE.

London, March 5, 1897.

Medical defence is quite a leading subject just now with a large section of the profession. Both the societies devoted to it have just held their annual meetings and the proposal for the British Medical Association to take up the work is being freely discussed. At the London and Counties Protection Society meeting the chairman remarked that though the society existed for the purpose of going to law, it was fortunate in keeping out of the courts during the past year. But he claimed that much good work had been done which could not be related in the report without doing harm to some of the people concerned. The reserve fund had been brought up to £344 and there is a guarantee fund of £1,700. At the meeting of the Defence Union success was measured rather by the number of actions brought to a satisfactory conclusion. In this respect the union has done a great work, and promptitude in movement has been one of the chief causes of its success. Mr. V. Horsley, F.R.C., presided, and threw the responsibility of the failure of the proposed amalgamation on the London and Counties Association, which had abruptly broken off the negotiations on the point of the name of the amalgamated society. It really seems a pity, as I remarked at the time, that an an arrangement cannot be come to, for "what's in a name?" Surely in such a case union is strength. Mr. Horsley has always been, he said, in favor of amalgamation and he has worked hard as president of the union. It is a question whether even yet negotiations may not be renewed.

But the much larger proposal of union with or absorption into the British Medical Association is now fairly before the profession. The advocates of this are numerous and active. The officials seem to wish to be led rather than to lead, and a scheme has been submitted to the branches and is under serious consideration by them. Under it the association would take up the work of defence, and an additional subscription would be levied for the purpose. This, which should be regarded as a premium for insurance, does not seem to satisfy all members. Some think it should not be compulsory. Others say if it were only voluntary, many members would omit to pay it. In that case there would be no advantage over the present societies. But if all were compelled to subscribe, there would be a splendid fund available for defence. Some fear that compulsion would cause numerous secessions and so weaken the association. The branches will not be unanimous. In fact some have already pronounced in favor of taking up defence and others against it. No little discussion is therefore going on, and perhaps this may eventually lead to something approaching unanimity. If the association takes up the work it will probably absorb both the smaller societies, and special provision should no doubt be made to facilitate this. It was suggested at the meeting of the union that some of its members, not belonging to the association, would find themselves deprived of their present benefits, and it certainly looks as if a little hardship might be the result in some cases. If so, they would have to comfort themselves with the reflection that they had contributed to the establish-

ment of a much greater fund for defence than the union is likely to command.

There was a meeting this day week at the Royal College of Physicians of the delegates named in the report of the Cowper commission on the University of London. Lord Lister moved a resolution, calling on the government to take immediate steps for the reconstruction of the university on the lines recommended by the Cowper commission. The motion was seconded by Professor Rucker and supported by Sir George Young, Sir H. Roscoe, the Rev. Dr. Wace, and Lord Reay. It was carried unanimously. Other movements in favor of a teaching university are being renewed; among them the medical schools will be forward, for their interests are deeply involved.

The annual meeting of the Medico-Chirurgical Society was held on Monday. It is as solemn a function as becomes our premier society. The financial statement and the library report were considered satisfactory. The president (Dr. Dickinson) gave his address, in which, having referred to the increased number of fellows and the finances, he spoke of the house dinner held last year as a pleasant institution, which he hoped might become annual. Then, as in duty bound, he took up the death roll—this year a heavy one, for the society has lost twenty-three ordinary fellows, three of whom had been presidents and seven fellows of the Royal Society. One honorary fellow, Prof. Du Bois-Reymond, has also died in the year. Some feeling tributes were passed to the deceased fellows, most of whose deaths I have reported as they occurred. The usual vote of thanks was passed for the address and the officers for the ensuing session were elected.

The physiology of the foot seems in need of clearing up, at any rate from a surgical point of view, if we may judge from the proceedings at the last ordinary meeting of the Medico-Chirurgical Society. Mr. T. S. Ellis has been insisting for years that the plantar arch is formed and maintained by muscular action and so may be thereby renewed after destruction. The point he now brings forward is, Why is the arch not overformed in stage dancers? He says the short flexors keep the great toe in a straight line and counteract the excessive action of the long flexors, which naturally tend to increase the arch. He exhibited a wooden model of the foot provided with elastic cords to imitate the action of the muscles—one set of which he calls "formators" and the other "limitors" of the arch. He regards hollow foot or claw foot as a consequence of persistent action of the long flexors with failure of the short flexors and the adductors. On the other hand he attributes flat foot to failure of action in both groups. He is convinced that the hanging foot at rest is in the position of inversion, and there is great strain and loss of power in walking with the foot everted. Consequently he urges that our military march should be altered. He says the action of the flexor longus hallucis can be shown to throw the ankle outward by putting the toes together and rising on tiptoe. Objection was taken to the view that the flexor longus throws the foot outward as well as to some other opinions, and of course it was remarked that the model, however carefully contrived and made, could not fully represent all the conditions in the foot.

The meeting of the Clinical Society on Friday was devoted to the exhibition of cases, of which there was a fair show. There was a young man with multiple subcutaneous tumors, apparently fibro-neuromata, which had been noticed for years. An osseous growth from the left frontal bone appeared three years ago and last year nervous symptoms came on, pointing to growth inward, though it is possible they may be set up by tumors pressing on the cranial nerves and spinal roots.

A girl, aged fifteen years, was shown, the subject of hystero-epilepsy, who has periods of double consciousness, which first came on after an attack of meningitis. Her case was reported to the society a year ago and no change has occurred in it.

A man, aged thirty-three years, had had a hæmatoma of the left auricle which had developed spontaneously and subsided without the usual scarring.

Dyspnœa is not common in aortic cases with brachycardia, but a case of this complication was exhibited. There had been a systolic murmur, but within a few days a diastolic murmur had developed. Other cases were mentioned in which a diastolic murmur had developed after a time. Such cases seem to be rare. A man, aged forty-two years, with aneurism of the aorta, was shown by Dr. Besley Thorne, who had treated him by mineral baths and graduated exercise with free ingestion of fluids. After six weeks he could walk with comfort, although prior to treatment the slightest exertion caused great dyspnœa. A skiagraph was shown. The aneurism had not increased in size during the exercises. A slight recurrence yielded to renewal of the treatment.

Another case suggested an association of scleroderma with Raynaud's disease—a circumstance observed by Raynaud himself. An infant with a syphilitic eruption was shown, and a man with ulcer on the leg, healing gradually after incisions at the outer edges and bringing the inner edges together in the middle line. The gaps were treated by Thiersch grafts.

Sir Blundell Maple has subscribed £100,000 toward rebuilding University College Hospital.

The Dublin epidemics continue.

The midwives registration bill has been postponed to the 12th and will then have little chance of coming on.

Surgeon Fyfe, R.N., was the only officer killed at the taking of Benin. He was shot while attending Captain Byrne. He was "only a non-combatant," and the so-called combatants assume superiority to such brave helpers.

OUR BERLIN LETTER.

(From our Special Correspondent.)

THE PEST QUESTION—MEDICAL CONGRESSES—A NEW WRINKLE FOR LARYNGOLOGISTS—PHYSICIANS AND QUACKS—NUMBER OF PHYSICIANS IN GERMANY, ETC.

BERLIN, March 10, 1897.

NOTWITHSTANDING the plague in India has apparently passed the maximum degree of virulence, the German government, as briefly indicated in my last letter, has taken energetic steps to prevent its introduction into this country. To begin with, it has sent a commission composed of experienced scientists to India to study the nature of the plague, and to obtain if possible an anti-plague serum. Strict quarantine precautions against vessels from the stricken districts have been taken. All vessels that have persons on board suffering from the plague at any time during the voyage, or have any "suspects," are detained, and the sick, the "suspects," and the well passengers are placed in separate buildings. Unsuspected persons are detained eleven days, invalids until final recovery, and "suspects" until the period of incubation is well passed. A vessel coming from the plague region with a clean bill of health is passed after the passenger baggage is disinfected. Similarly strict precautions have been adopted by all other European countries as well, so that the danger of the conveyance of the plague into America via Europe is, to say the least, very remote. It remains for America to protect itself by strict quarantine measures from any

invasion, especially over the Pacific coast from Australia and Eastern Asia. How active the interest in Berlin medical circles in this question is was recently demonstrated by the unusually large attendance at the Berliner medicinische Gesellschaft on the 24th ult., when Dr. Rolle read a descriptive paper upon the subject. With the projection lantern, he demonstrated microscopic preparations of the plague bacillus from patients and animal experiments, and also showed cultures of the germ.

The plague conference in Venice was touched upon in my last letter. Berlin will witness two medical congresses in the near future; viz., the balneological, to be held from the 11th to the 15th of March, and that for practitioners of internal medicine, to be held from the 9th to the 12th of June. To both of these all American colleagues are cordially invited.

A new trick to prevent the disagreeable coating of laryngoscopical mirrors with moisture is worth noting. Dr. Kierstein, the discoverer of the autoscope, was the recipient recently of a secret remedy said to prevent this coating, and which looked like softsoap. Indeed the resemblance was so striking that softsoap was tried, and behold, it fulfilled the same purpose. Even direct breathing upon the mirrors will produce no moisture. The same holds good of microscopic lenses. Practically the procedure is of little value, for the customary preliminary warming of the mirror before using is less troublesome for the physician, and certainly more agreeable for the patient than softsoap. Still it is an interesting physical fact, and it is therefore worthy of mention.

It is the aim and desire of the German physicians to keep the professional tone and standing even cleaner and brighter than their laryngoscopical mirrors. It is a lamentable fact that Germany abounds with quacks and "healers." This is the result of a lax state of laws which permit any one who so wishes to practise the healing art. Medical practitioners are not regarded as a special professional class, but are classed with the trades and industries. It is the earnest endeavor of all physicians here to have the dignity and privileges of their science and profession formally recognized by law. Included in such a recognition would of course be suitable protective measures against quackery. This end was, and still is, being striven for by our foremost academic teachers, Kussmaul, Bardeleben, Gerhardt, von Ziemssen, and others. They favor a more rigid medical examination, and say that especially should the examination in the branches of hydrotherapy, psychiatry, and in the treatment of accidents and injuries be more severe. In Germany one obtains his degree of doctor of medicine at the universities, but any one can practise as a physician who passes the "Staatsexamen." The study at the universities is long (five years) and expensive; the increased severity of the examinations would result in many attending but a year or two and then beginning practice. What is necessary is stringent laws against quackery. At present this is out of the question, for these individuals seem to have protection from the higher circles. It is a fact that a general suffering from tabes dorsalis was treated in a local hospital by a quack, and the visiting professors were forced to permit him under their very eyes to apply daily his special "methods" until he had succeeded in "curing" his patient forever, which sad event took place in a brief space of time.

The greatest and best-known of all quacks is the celebrated Pastor Kneipp, who still flourishes here. It is admitted that there is much good in his peculiar methods, but the general world will never learn how much harm has been done by the irrational, forced, and excessive application of the "Kneipp cure," by Kneipp himself and his overzealous, unreasoning imitators, because the victims dread the ridicule which would fall upon them if they complained. I will cite but one sad case as a sample of the total neglect of duty toward patients in vogue at the Kneipp Hospitals in Wörishafen. A young girl, who had been in several institutions because she was suffering from mental disease, was brought to Kneipp by her relatives as a *refugium ultimum*. From him she received the customary treatment of such cases. She was told that she was mentally weak, and frequently excited to violent insane outbreaks. Then the following awful, unheard-of procedure was gone through with. This young, weak-minded emotional girl was placed in charge of a young orderly at night. The consequences were not failing. The patient was in course of time delivered of a child. It was of course impossible to prove the guilt of the orderly in court, but the persons responsible for the care and treatment of the patient will be proceeded against by law. However, the root of the evil lies in the laws themselves, which give free license to quacks, and thus permit the unrestrained practice of the "healing art" as it is carried on in such grand style at Wörishafen.

Not only is the profession unprotected by the law, but directly oppressed. As related in a preceding letter, the tax authorities have determined to levy an assessment upon all private clinics. Under the leadership of von Bergmann, a society of physicians has been formed to combat by all legal means this unjust measure against physicians.

The medical profession in Germany is notoriously overcrowded, and in view of this it can be easily understood how doubly oppressive the workings of the law must be. In November, 1896, there were 24,000 physicians (practitioners) in Germany: an increase in the last decade of 8,000, or, in other words, 34 per cent. In Berlin itself, the number was 2,077. The average of physicians to the population equals 459 per 10,000 (in Hamburg it equals 742). It is interesting to note the increase of physicians and of the population at the same time. While the population of Berlin from 1890 to 1895 increased 6 per cent., the number of physicians increased 35.4 per cent.; while in the German empire the population increased 5.7 per cent., the number of physicians increased 22.5 per cent. Should this go on for twenty years more, the prospects for our successors certainly do not look rosy. A reform of all the factors which now conduce to lower the standing and dignity of the medical profession is an absolute necessity in order to prevent it from sinking to the level of the trade.

DERMATITIS ATTRIBUTED TO *X*-RAYS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Referring to Dr. Lilienthal's letter (MEDICAL RECORD, February 20, 1897, p. 287), I am glad to see that the suggestions put forward by me in a communication of December 31, 1896 (MEDICAL RECORD, January 30, 1897, p. 178) are confirmed by Mr. Tesla.

In my remarks I questioned whether the skin manifestations were due to the *x*-rays at all, and suggested that the dermatitis was probably the result of the action of obscure heat waves. I further pointed out that in the cases recorded, the exposure had either been prolonged or repeated at frequent intervals. In conclusion, I stated it would be worth while to place a solution of alum in water between the Crookes tube and the patient, with the object of absorbing the heat-waves, without interfering with the *x*-rays.

In a recent letter to Dr. Lilienthal (*loc. cit.*) Mr. Tesla expressed the opinion that he had gained additional evidence that the *x*-rays themselves were incapable of producing the actions reported, and that

they were due to ozone and possibly nitrous acid. He added that heat also might be to a certain extent responsible. This latter view he, however, further emphasized by stating that the effects followed long exposures at short intervals, and that he believed the long-continued heat might cause desiccation of the skin with subsequent dermatitis. To protect the patient he recommended an aluminium screen, which would allow the *x*-rays to pass through but stop chemical substances.

From the above *résumé* it will be seen that Mr. Tesla shares the views expressed by me on the subject of so-called Roentgen-ray dermatitis.

BRITISH MEDICAL ASSOCIATION, MONTREAL MEETING.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: We regret to hear from friends across the border that your editorial of February 20th, upon the coming meeting of the British Medical Association in Montreal, has created no small amount of irritation and we may almost say misunderstanding among members of the profession throughout the United States. What is said in that editorial is strictly correct, and we are glad that you have drawn attention to the conditions under which those who are not members of the association can attend the meetings of the same, for thereby you have taken from us the extremely unpleasant burden of directly notifying our confrères that we cannot invite the whole individual profession of America to take part in the meeting.

Nevertheless, we are greatly concerned that the very delicate position in which we find ourselves has caused irritation, and are most anxious to remove as far as possible all ground for soreness. We trust that what follows will prove that we are far from preparing to hold a "little family feast," and that we are doing all that lies in our power to have with us as many friends as we can safely invite.

While the British Medical Association has a membership of close upon twenty thousand, the attendance at any previous gathering has but on two occassion reached three thousand. The majority of the members reside in the British Isles, and under the most favorable circumstances we cannot expect that great numbers—thousands—of members will attend next August. The extent of steamship accommodation alone prevents more than a few hundred old-country members being present with us. Canada with her sparse population will be represented by hundreds and not thousands of members; the other British colonies and dependencies by delegates from the various branches; and were we to throw the meeting open to the medical men in attendance upon the sixty-six million inhabitants of the United States, the members of the association present would be utterly swamped by the non-members. The whole character of the meeting would be destroyed—it would no longer be a meeting of the British Medical Association, but would assume the nature of an American medical congress with British officeholders.

Clearly, our confrères across the line will see that, even were we guided by no bylaws, we in Montreal, having secured the first gathering of the association outside the British Isles, dare not venture to change the whole character of the annual meeting. Add to this that to throw the meeting open would of necessity make us guilty of holding an international medical congress in opposition to that which will be held in Moscow this year. For the honor of the profession, as also for the grave political considerations, we dare not lay ourselves open to this charge.

All that we can venture, all that can in reason be expected of us, is to invite as guests, not the whole profession in the States, but the leaders of the profession. For weeks, not to say months, we have been engaged in drawing up with great care lists of representative men in the various branches of our profession in various States of the Union: and the sole reason why our invitations have not already been dispatched is that we wish to invite as many as we can, but cannot enlarge these lists until we have a more definite idea of the number of old-country members who will attend. That is to say, we wish to invite the greatest number possible without endangering the character of the meeting. We expect to have not less than one thousand members present, and thus our list of invited guests will assume no inconsiderable proportions. We are, dear sir,

Yours very faithfully,

J. G. ADAMI, M.A., M.D.,
J. A. SPRINGLE, M.D.,
E. P. BENOIT, M.D.,
Honorary Local Secretaries.

VOMITING AND INTUBATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: My attention has been called to the interesting letter of Dr. Thomas Hubbard, in your issue of the 6th ultimo, and the no less interesting reply of Dr. J. O'Dwyer in that of February 20th. Neither communication, however, quite reaches the heart of the question originally raised by my paper, nor do they much affect the physiological theory of vomiting, inasmuch as they deal only with intubation practised with the ordinary tube.

Dr. Hubbard has quoted me as having suggested intubation as a means of checking hyperemesis, and this fact, together with a deep anxiety to see my theory put to the practical test, prompts the present communication.

In an article[1] published in the *Medical News* of July 6, 1895, I called attention to the fact that if physiologists were correct, the important factor in efficient emptying of the stomach was, so far as the actual mechanism is concerned, the firm contraction and fixation of the diaphragm, and that this depended upon the rigid base of support afforded by the expanded ribs, being due to forced and held inspiration, the fixed air column in the trachea being absolutely necessary to the proper performance of the act; that, assuming this to be true, we might hope to prevent vomiting, either by intubation or by tracheotomy in desperate cases, by making it impossible for the patient to hold the forced inspiration. Further, that the tube used must probably be especially designed for this purpose, as the outlet of the ordinary tube could perhaps be closed by the epiglottis and the tissues in which it lies.

A special tube devised by me to meet this indication was figured in that article. This tube has a very high head, with a large opening on its posterior as well as its superior surface. The possible adaptability of such a tube to the relief of intractable hiccough and to pertussis was also mentioned. Unfortunately, as Dr. O'Dwyer states, physiological theories and working facts are not always in harmony, and no one can feel more keenly than I the need of a practical test and the testimony afforded by a long series of observations.

[1] A suggestion bearing upon a new method of treatment of persistent vomiting.

No man living has had a greater experience in this line of work than has Dr. O'Dwyer, and I trust he will give the theory a trial, not through the use of the ordinary tube, but with some such modification as I have recommended. Such tubes are to be obtained from Tiemann at the present time, but those that I have are a bit too long in the shank, and would be better if made of vulcanite instead of metal, as has been suggested by Tiemann. I should like to ask the doctor if he has ever observed that true vomiting occurred after tracheotomy when the tube introduced into the trachea was of good calibre and free from obstruction. I have questioned a considerable number of physicians, surgeons, and nurses, and have been told almost invariably that vomiting has never occurred after the operation, so far as they can recollect. For the present purpose, observations upon adults would be particularly desirable.

Dr. O'Dwyer overthrew many theories when he demonstrated his novel procedure to a somewhat incredulous profession, and I trust that in this matter his invaluable services may be enlisted, having in view the possible establishment of a new application of his own great discovery.

CHARLES LYMAN GREENE, M.D.

ST. PAUL, March 7, 1897.

WOMAN'S INFERIORITY TO MAN—MAN'S INFERIORITY TO WOMAN—WHICH IS SUPERIOR?—NEITHER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have recently read in the MEDICAL RECORD a certain article on "Woman's Inferior Sensitiveness to Pain," from which a certain doctor (Ottolenghi) attempts to prove woman's inferiority to man. As I am a woman, I may be excused for entering a protest and also for expressing some very strong feeling on the subject. To say that I was disgusted, would hardly express my feeling. I knew on first reading it, however, that the argument was misleading, though I did not then have the material at hand with which to defeat it. But I have now. His argument is a fallacy, and I am going to prove it. Hear him:

"Women are less sensitive to pain than men. The higher classes are most sensitive and the uncivilized and degenerates least. And, therefore, as the uncivilized and degenerates are least sensitive to pain, and as woman is less sensitive than man, woman is inferior."

I shall prove the fallacy of his analogy, and that by making another. I am going to prove by my analogy that man is inferior to woman.

Man has more physical strength or brute force than woman The higher classes have the least and the uncivilized and lower classes or (races) the most. And, therefore, as it is the uncivilized and lower classes (or types) that have the most brute force, and as man has more than woman, therefore man is inferior to woman.

But I do not think so. I merely wanted to show the fallacy of his argument. And I have shown it. I would be glad if you would publish this. Although I am not a physician, and am a woman, still I give myself the credit of having some sense. I really do think it is a duty you owe to your readers and to the world at large to publish this, for nothing is like a mistaken notion for doing harm.

For the benefit of those who may be too simple to comprehend, I will say that the negro has more brute force than the white race. So with all the other inferior races, I suppose. But it is certainly true in regard to the negro.

Of course it is needless for me to say that I do not accept the views recorded of the distinguished doctor. I never could look upon our sex as being inferior to the other. It seems to me that nature herself would teach us better. Among the lower animals we do not look upon one sex as being inferior to the other. Why should man be an exception? Nowhere in all creation is the male considered superior to the female, and I do not believe it right or just to make woman, the rightful and lawful consort of man, his inferior. It is only the self-conceit of man that allows him to do it.

I could say a great deal more, but I will not waste my time on it. This much I have said, and this much I mean, and I shall send it to you, whether you publish it or not.

But this much I will add. It may be that woman's so-called "inferiority" is due to her "inferior" opportunities. This you might do well to ponder.

Whenever and wherever I see more mistakes in your magazine, I shall not only consider it my privilege but my duty to inform you of them. . . . I suppose, however, as I am not a "learned doctor," this will not be published.

Another analogy: Men are less refined than women; among the higher classes is the most refinement and among the lower classes and degenerated least. And, therefore, as the lower classes and degenerates are least refined, and as man is less refined than woman, therefore man is inferior.

MATTIE MITCHELL.

[We gladly give our correspondent an opportunity for expressing her views, and gallantly acknowledge the force of her arguments.—ED.]

NERVOUS INFLUENCE AND DISEASES OF WOMEN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the course of a recent most interesting discussion before the College of Physicians of Philadelphia upon the causative influence of gynæcological diseases in the production of diseases or derangements of the nervous system, the weight of evidence seemed to be negative; those who were not influenced by the fact that they were gynæcological surgeons seemed to think that nervous derangements are not so generally dependent upon gynæcological diseases and that their relief does not so frequently follow gynæcological operations as many of us have been taught to believe. Now, I am tempted to ask whether the reverse is not the case: whether many gynæcological diseases are not directly or indirectly dependent upon a primary derangement of the nervous system.

Regarding, as we must, the nervous system as the great vivifying, controlling, regulating department of the body, realizing that without the force elaborated in and disseminated from the nervous system the organs of the body would be but inanimate masses of organic matter; remembering that, without nervous force, manifestation of function would be impossible, is it not more logical to assume that disorder is more likely to originate in the nervous system than in some organ (as the uterus or ovary) that of itself has no inherent power, no capacity of originating or perpetuating either normal or abnormal action? Is it possible for any organ of the body to become diseased without a previous derangement of the all-controlling nervous system?

Would it not be well, therefore, in all gynæcological diseases to look into the condition of the nervous system and to combine with our local treatment measures calculated to restore this system to a normal condition?

Would it not be well in all gynæcological cases fairly to try the therapeutic efficacy of a restored nervous system before resorting to surgical procedures?

Joseph F. Edwards, M.D.

THE TOXIC ORIGIN OF INSANITY.

To the Editor of the Medical Record.

Sir: In the New York *Herald* of to-day appears a sensational article with the caption "No Longer a Mystery." It purports to be the discovery of the toxic origin of insanity determined by the bacteriologists of the State Institute of Pathology, and it contains a covert puff for the State commissioners in lunacy.

While the fullest credit should be given to the staff of this important institution, it is but fair to state that the study of toxæmia in connection with insanity is by no means a novelty, nor is it the discovery of these enterprising young gentlemen. Over a decade ago Salomon, Regis, and others recognized the toxic origin of mental disease, while no less than ten others, among them Herter and Smith, have written extensively on the subject. Perhaps most credit should be given to Dr. Allan McLane Hamilton, whose paper on "Autotoxis as a Cause of Insanity" was read before the Medical Society of London in May last, and noticed in your London letter a short time subsequently. In this paper, which contained much original research, the connection between toxæmia and insanity was fully shown.

Vesania.

New York, March 15, 1897.

IS ORTHOPÆDIC SURGERY TO BECOME AN OBSOLETE SPECIALTY?—WITH REMARKS ON SPECIALISM.

To the Editor of the Medical Record.

Sir: No one interested in the advancement of true specialism in medicine can fail to thank you for your editorial, "Is Gynæcology to Become an Obsolete Specialty?" which appeared in the Medical Record of February 27, 1897.

Aside from the merits of the questions raised by the discussion between the surgeons and the gynæcologists, the more important issue is, Is it the best policy, both from a scientific, medical, and humanitarian standpoint, for any special department of medicine to "overlap" and invade other fields? All will admit that this is in many instances a necessity as a matter of study and education. But as a matter of practice it would seem to be an error. In a humble way I have discussed this subject elsewhere when my essay, "What is Orthopædic Surgery?" was criticised by Dr. Gibney in the *New York Medical Journal* of November 7, 1891. In my reply[1] to Dr. Gibney I say: "It is universally admitted, I think, that all specialists in medicine should be thoroughly equipped both in medicine and surgery, and there is no reason why one thus equipped should not practise both general medicine and surgery. It must, however, be apparent that the so-called specialist who does this weakens his own claim to specialism and apologizes for his specialty. This will be true so long as medicine and surgery, generally speaking, are progressive, and so long as there are unsolved truths awaiting the special investigator and the special student."

Have the specialists solved all the truths in their special departments? How many have ceased to be special investigators as well as special practitioners?

Unless these questions can be otherwise satisfactorily answered it would seem that the answer made to Dr. Gibney regarding orthopædic surgery is also applicable to other specialties.

I do not stop to question the motives of those who "overlap." They may be honest but mistaken, or they may be selfish or "commercial." But it is a fact that the effect of the present state of affairs upon the entire medical profession is bad, and I have noticed that the lay public is beginning to ask: "What sort of a specialist is he who in his office, in his writings, and in his college and hospital work is a specialist, but who is a family physician and a general practitioner among a selected *clientèle* on other occasions?"

The outlook for the general practitioner is indeed an uncertain one if the "specialist" is to invade the domain of the family physician. Why should he do so?

Not long ago, for example, I had occasion to send a gentleman who consulted me to a well-known specialist. With my full approval this specialist took entire charge of the conduct of the case. He is now duly installed as the regular medical attendant of not only the patient himself, but of his immediate family and some of his friends. I frankly told the "specialist" that I was surprised at his course, but he only smiled and said, "Others do it."

This is no excuse. As I have often said to those who have honored me by asking my advice regarding the adoption of a specialty: "One can make no better investment of one's time after a thorough training, than gradually to adopt a specialty when opportunity or inclination favors. When, however, a certain point is passed, or a hospital or college position, presenting an opportunity for clinical study and investigation, enables one to assume a position as an authority, one should, if he adopts a specialty, cease to be a general practitioner."

The demoralization which has apparently invaded the gynæcological field has already left its marks on orthopædic surgery, and the remarks made in your editorial, with a slight change of words, are applicable to quite a number of men who are best known as orthopædic surgeons. Not content with a patient study in the wide and practically unexplored field before them, these "orthopædic surgeons" "overlap" and, neglecting legitimate orthopædic work, invade the field of the general surgeon.

There are orthopædic surgeons to whom even laparotomy is not a stranger. A considerable portion of a chapter in a recent work on orthopædic surgery is devoted to "amputation at the hip-joint." A paper read before the American Orthopædic Association and published in its Transactions is entitled "Amputation as an Orthopædic Measure." One man, until quite recently a member of the Orthopædic Association, resigned because he felt that he could not afford to have it known that he was connected with the association. Other good and able men, starting out with the intent and desire of becoming orthopædic surgeons, have failed to have the "courage of their convictions" at a critical moment and have become in effect general surgeons. And the profession smiles and the communities in which they live cannot see any great difference between the general surgeon and his orthopædic competitor.

Orthopædic surgery is bound to become a great specialty, but it will not succeed on general surgical lines. Before it can be a real specialty it must cease to appear in the rôle of a competitor with general surgery. It must not "overlap." Its disciples must cease to antagonize the best elements of the profession by posing as orthopædists, when they only lack opportunity to become general surgeons. And until this change is brought about there will be no true orthopædic surgery, except as here and there a man

[1] "On the Definition and Scope of Orthopædic Surgery," New York Medical Journal, November 14, 1891.

stands up for the right and defies criticism, for it is getting to be almost as rare to find a legitimate orthopædic surgeon as it is to meet with an orthodox gynæcologist who does not "overlap" and compete with the general surgeon in operating for appendicitis, etc.

Many do not, I think, appreciate how much there is in orthopædic surgery, outside of its somewhat limited operative work, or how far it may be made useful to humanity. It certainly cannot aid the orthopædist to compete with the general surgeon, and, indeed, there is no necessity for it. If it were accepted and understood by the profession at large that the orthopædic surgeon should confine his operative work to those cases which require special orthopædic care after operation, the entire profession would be benefited: orthopædic surgery would find itself busy with congenial work, and it would occupy a well-defined and enviable position among the specialties.

NEWTON M. SHAFFER, M.D.
32 EAST THIRTY-EIGHTH STREET, NEW YORK,
March 10, 1897.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 20, 1897:

	Cases.	Deaths.
Tuberculosis	161	107
Typhoid fever	5	2
Scarlet fever	200	10
Cerebro-spinal meningitis	2	4
Measles	187	9
Diphtheria	230	37
Laryngeal diphtheria (croup)	14	3
Small-Pox	3	0
Chicken-pox	12	0

A New Application for the X-Rays.—According to the *Journal de Médecine de Bordeaux*, a man by the name of Ferdinand, placed under arrest for illegal practice of medicine, claiming to be a graduate of an American college, presented a diploma which excited the suspicion of the magistrate. Calling in the services of an expert, the document was submitted to the action of a Crookes tube, and the resulting skiagraph showed distinctly the outlines, in the substance of the paper, of a name which had been erased from the surface to make room for that of "Dr. Ferdinand," who was held upon this evidence.

Professor Kölliker will celebrate, on the 6th of July next, his eightieth birthday and fiftieth anniversary as a teacher of medicine.

Fürbringer's Statistics for the Antitoxin Treatment during 1896 show 663 cases, with 114 deaths, or a mortality of seventeen per cent. In the year preceding there had been 581 cases in the hospital, half of which only were subjected to the serum treatment, and the mortality had been over thirty per cent. Only one accident resulted from the injections. In a child of seven years, syncope, lasting two minutes, followed what was supposed to have been an injection into a vein. By the employment of violent revulsive agents, the child was brought back to life.

Health in Texas.—The report of the health officer, Dr. Swearingen, for 1895-96, just received, shows an interesting outbreak of small-pox among negro refugees from Mexico. At the quarantine established at Eagle Pass 411 were detained, 178 of whom had variola, and of which number 51 died. In an epidemic of scarlatina of atypical form, not recognized as such for some time, 44 cases occurred in 17 families, with 11 deaths (twenty-five per cent.). There is also a report upon the shipment of cattle during the quarantine season.

Insusceptibility to Vaccination has a legalized status in England, and many certificates are granted each year. The last report of the local government board shows, however, that in 88,875 successive vaccinations, not a single instance of insusceptibility had been met.

Swine Fever is not always the same disease in different epidemics, and it is not impossible, considering Behla's recent experiments, that a certain proportion of the instances are due to the same infectious agent as produces measles in the human.—*La Médecine Moderne.*

A New Laboratory.—The raw material of ichthyol, heretofore found only in the Tyrol, has recently been discovered on the Adriatic coast, and the yield of the material is said to be extremely rich.—*Medical Press.*

State Examining Boards.—Let every State have its examining board, but let there be also such uniformity of requirement that when a man has passed his examination in one State he may be permitted to practise in any State of the union to which force of circumstances or inclinations have driven or led him.

The Way They Treat Quacks in Germany.—A Dusseldorf "doctor," found guilty of selling nostrums for all kinds of disease and of advertising "cure alls" and similar impositions, has been sentenced to four years' imprisonment, to pay a fine of £150, and to a suspension of his rights of citizenship for five years.

Quinine Packets Made in Indian Prisons.—Quinine packets containing five grains each are made up in the prisons. During the past year, in the Alipore central jail, 3,760,434 powders were filled and packed, giving employment to a daily average of 29 prisoners; during the previous year only 2,917,536 were folded. The total number of post offices supplied with these packets in Bengal alone increased during the year from 2,321 to 2,509, and out of that number only 127 have not replenished their original stock, showing how much the packets are in demand.

Rabies has increased in England since the law relating to muzzles for dogs was repealed in 1892. There were 38 cases that year. In 1893 there were 93 instances; in 1894, 248; in 1895, 672.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that it necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

ON THE DISINFECTION OF THE HANDS.

By ROBERT F. WEIR, M.D.,

SURGEON TO THE NEW YORK HOSPITAL; PROFESSOR OF SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

THE riddance of hurtful germs from whatever the surgeon or his assistants may put into or apply to a freshly made wound has been of late years simply and satisfactorily made, save in two exceptions.

By the application of dry or moist heat, sterilization, proven to be perfect, has been easily accomplished in the dressings, instruments, pads (in lieu of sponges), and ligatures, excepting catgut, which in its larger strands is yet infrequently imperfectly sterilized. This is one of the exceptions alluded to. The other and more important one, and to which the remedy of heat cannot be applied, is the required aseptic condition of the hands of the surgeon and his assistants and also of the operation field itself. This is yet the weak spot in our aseptic work, and numerous attempts have been made to gain both certainty and simplicity in this direction. I cannot in the few minutes allotted me spare time to go over all the methods that have been proposed, and shall only attempt to bring to notice sundry tests that, through the aid of my house surgeons, Drs. Kenerson and Taylor, and their staff, I have been able to conduct, at the New York Hospital, during the past three or four months. Casting aside a long list of antiseptics that have been shown to be ineffectual, there remain a few that have been more or less freely accepted by surgeons from the test of a long or rigid experience. Of the oldest are carbolic acid in 1 to 20 solution, and the bichloride of mercury, in solutions varying from 1 to 500 to 1 to 5,000. Both of these are objectionable, from the secondary reason of the skin irritation and roughness that they often produce; but it was not long after the introduction of carbolic acid into surgery that it was found clinically that the carbolized oil and alcohol solutions were unreliable, and as early as 1881 Koch[1] gave the true reasons for such discredit, and further proved by culture tests that even the strong watery solution, 1 to 20, of the acid was not always to be depended on as a germicide. This conclusion has been shown to be correct by many other observers since that time. The new antiseptic, the corrosive sublimate of mercury, then came into vogue and reigned supreme for many years as an efficacious, cheap, and readily attainable germicide; and though disinfection by heat, announced as early as 1881 by Koch, gradually displaced the sublimate disinfection for all wound paraphernalia, still it required additional and further knowledge to drive away all antiseptic irrigations or applications to a freshly made wound, and to substitute, in other words, asepsis in an operation for antisepsis. But, notwithstanding this, the sublimate solutions continued to hold their ground strongly as the best means for rendering sterile the hands entering a wound, until Geppert, in 1889 and again in 1891, showed that hand disinfection by such solutions was an error. For, by washing the hands, after being duly immersed for many minutes in a sublimate solution, with a solution of the sulphide of ammonium, which neutralizes the bichloride remaining on the hands, the scrapings from the hands and nails showed that in a large proportion the germs had not been killed, and that they would then be developed, without hindrance, in the culture tubes and, by inference, in the wounds into which they might be introduced. These experiments were corroborated and made more widely known to the surgeons of America by Dr. Abbott,[2] at the laboratory of the Johns Hopkins School at Baltimore, and have been confirmed by other observers many times since. Following upon this revelation, attempts were made either to employ new methods or to remedy, if possible, the faults of the sublimate solutions: as, for instance, by adding to its use, at the suggestion made by Fürbringer,[3] alcohol, to bathe or to brush with which under the nails and also along the edge of the skin at the root of the nails, for these two locations had been proven to be hardest to render germ free. With this addition the improved sublimate disinfection was carried out according to this formula: (1) Cleansing the hands with green soap and hot water, with strong brushing for one minute; (2) cleansing under and about the nails, preferably with a piece of soft wood; (3) one minute brushing or immersion of the nails in alcohol; (4) one minute immersion in a 1 to 2,000 sublimate solution. This procedure varied a little according to the surgeon, and generally more time was allotted to the soap-and-water scrubbing and to the sublimate immersion than was given by Fürbringer, and with myself the immersion was carried up to five minutes in a 1 to 1,000 solution, for the reason that I found that when the hands were then washed with sulphide-of-ammonium solution I was many times germ free on a culture test, though not invariably so. It seemed to me then, however, the best yet attainable. This I now see was probably due to not increasing the duration of the sulphide washing, and perhaps also to the influence of the alcohol. A new method was put forth about this time by Dr. Howard Kelly,[5] based upon Abbott's report on the unreliability of sublimate solutions, which has been tried faithfully not only by myself but also by many others, and not always with satisfactory results. I refer to the employment of the saturated solution of the permanganate of potassium,[6] in which, after the usual preliminary washing and brushing with soap and water, the hands and arms are immersed until they assume a deep mahogany-red or black color: they are

[4] Abbott: Johns Hopkins Hospital Bulletin, April, 1891.

[5] Poten, for example, recently repeated these tests of sublimate disinfection with subsequent washing out in the sulphide of ammonium solution in twenty-one instances, and in no case did the culture tubes remain free from germs.

[6] Fürbringer: "Untersuchungen und Vorschriften über die Disinfection der Hände."

[7] Kelly: American Journal of Obstetrics, etc., p. 1,414, 1891.

[8] The permanganate is added in excess to boiling water, i.e., beyond twenty-five per cent. The solution used at the New York Hospital is one part of the permanganate to sixteen parts of water.

then at once transferred to a saturated solution of oxalic acid, until completely decolorized and of a healthy pink color; a final washing with sterile water completes the procedure.

Kelly claimed a germ-free result in forty-four instances out of fifty trials. An unfavorable report on the method was, however, made by Reinecke, and my own culture test trials with it, shortly after an account of it had been published, showed me that it was not so satisfactory as was wished, and that the hands were at times left in a condition of roughness and discoloration that often necessitated the declination of a dinner invitation.

To determine more satisfactorily its worth, I have, however, recently carefully made a series of thirty-one tests of the permanganate method, with the following results: Twenty-two tubes remained sterile and nine showed colonies of staphylococcus, or a success of seventy per cent. This method has been followed, I think, only to a limited extent in this city or elsewhere; but its surgical position has been overtopped by other procedures.

Surgical attention during the past two years has continued to be largely centred on this weak spot in our hand asepsis, and while many substances to this end have been intruded on our notice, yet only two at present seem to promise much, and these are alcohol and chlorine.

Alcohol itself is, according to Koch and others, not a true germicide. Germs, according to this master observer, could be kept one hundred and ten days in absolute alcohol and then be found alive and active. Furbringer's addition of alcohol to the sublimate disinfection of the hand and fingers led to further experimentation and testing in this direction, and the most important papers presented on this subject have been those by Reinecke[1] (1895), Ahlfeld and Vahle[2] (1896), and Poten[3] (1897).

A *résumé* of the labors of these observers can be briefly given. It amounts to this: that alcohol in its ordinary strength, ninety-five per cent. (above fifty per cent., Poten; eighty to ninety-six per cent., Reinecke), will render the hands—previously washed according to the usual rule with brush, soap, and hot water—germ free after a brushing with or immersion in that fluid for five minutes. For this testing of the efficacy of alcohol, the most resisting germs were employed—generally the anthrax bacillus; but Reinecke resorted to a more resistant one than this, and safer to himself and to his patients, should the sterilizing process fail—the bacillus pyocyaneus, and more commonly a bacillus found in catgut, particularly in the larger strands. It is allied to the hay bacillus, and is supposed to be derived from the grass or hay eaten by the sheep from whose intestines catgut is made—a fact that is not generally known. Globig and others have used for similar reasons even a still more resisting potato bacillus (bacillus mesentericus ruber and vulgatus), and most of the tests have been carried out with scrapings made by knives, by roughly sharpened flattened wires, by pieces of ivory or of soft wood or rattan, from under the nails and about the edges of the fingers or hands, normally dirty or purposely smeared with the ordinary pyogenic germs. Kelly states with much positiveness, concerning this latter point, that "the staphylococcus albus and sometimes the aureus are present in enormous numbers on the hands and about the nails of every individual associated with medical work in this community (Johns Hopkins Hospital). This is demonstrated in all the experiments I have conducted." Ahlfeld, Vahle, and Poten adopted this view in their tests; and in my own, to be given shortly, I have largely accepted this fact, though control experiments with intentional infection have been made by myself and nearly all observers with more or less frequency. Leedham-Green, likewise, in twelve tests made with hands in a normal state, found even after washing with yellow or soft soap and water and with the use of a nail cleaner, that in every instance many colonies of the staphylococcus albus and aureus, bacillus pyocyaneus, and others could be developed.

Reinecke's exactness is plainly manifested in his paper, and its deductions are based upon carefully planned bacteriological investigations and methods of examination.

With such explanatory remarks, and referring those more deeply interested to the original articles themselves, I can at once place before you the conclusions arrived at concerning the reliability of alcohol as a means of disinfection of the hands. Reinecke found with washing with green soap and hot water for five minutes, and then brushing with ninety-six-per-cent. alcohol for three minutes, followed by a subsequent immersion in sterile water, that nearly always an absolutely germ-free condition of the hands would result. He also stated that in an emergency a probably safe condition of asepsis could be brought about by simply scrubbing the hands and nails for five minutes with alcohol alone.

Ahlfeld and Vahle, by substituting for or rather adding to the brushing of the hands and nails, a washing or true immersion in alcohol, were enabled to secure a perfect asepsis in 87.2 per cent. of their numerous trials, though Poten, with weaker alcohol, sixty to eighty per cent., with less damage to the hands, for strong alcohol irritates, got what he called a safe asepsis in eighty-seven per cent. The latter preferred, however, to wash the hands in two or three bowls of alcohol or until its color remained unchanged, the first washing causing usually slight opalescence from loosened epidermis, etc.

My own trials of alcohol, verified with a duly conducted culture test, amount to twenty-four in number. They were made with the usual brushing and washing with green soap and hot running water, and with the aid of a pointed brush, like end of rattan, which aids best, I think, in cleaning under and about the nail spaces. This washing was done for from three to five minutes; then the hands were immersed in alcohol, ninety-five-per-cent. strength, and brushed vigorously for five minutes; occasionally a final washing of sterilized water was resorted to—more to aid by its moisture the subsequent scraping for products for culture tests than aught else.

Of these trials but one showed any germs in the agar culture tubes, though the hands were rendered very dry and roughened by the alcohol.

Not all the testimony that I have collected is, however, so favorable to alcohol as that just given. Mr. Leedham-Green,[1] in October, 1896, repeated the experiments of Reinecke on normal hands and hands artificially infected with bacillus pyocyaneus or with the potato bacillus; he also infected the hands with pus from an abscess, etc. His series of twelve each of the various infections showed that an aseptic condition, after the employment of the alcohol method of Reinecke, occurred on normally infected hands but twice; on hands purposely infected with the bacillus pyocyaneus, but once; with potato bacillus, tried six times, all remained infected. His results from other experiments with the sublimate solutions, repetitions of Geppert's, were so much at variance with the reports of that observer that he himself thought at first that his own methods might be faulty, but no error was found. In spite of these adverse results, he concludes by say-

ing that though alcohol will not accomplish all or nearly all that Reinecke and others claim for it, it is nevertheless a valuable if not the most valuable agent we possess for the disinfection of the hands.

As to the way in which alcohol produces sterilization, a good deal of discussion has arisen. It has already been quoted that germs kept one hundred and ten days in absolute alcohol have been found then to be active and capable of rapid development. This would seem to settle the point that alcohol was not an antiseptic, but its preservative qualities are too well known to admit of this doubt. Fürbringer said it removed the fat from the hands, and so gave subsequent disinfection a better chance to work. This is disproved by the fact that sterile fingers may be obtained by alcohol alone. Reinecke said that the grease in the hands held the germs *in situ;* the alcohol, dissolving the fat, allowed these germs to be mechanically washed away, particularly if sterile water was used after the alcohol. This does not fit, however; for when ether, which is equally a fat solvent, was used for two minutes to wash the hands, asepsis was produced in only 22.2 per cent. of the trials made, though when alcohol was similarly employed in the same series, 88.8 per cent. of the hands were rendered aseptic. Kronig, who had bad luck with his alcohol tests and whose experiments do not stand criticism, thought the alcohol so shrunk together the scales of the epidermis by its hygroscopic properties that the bacteria had no chance to get into the test gelatin when the fingers were pushed into it. But, without quoting further opinions, the explanation offered by Ahlfeld and Vahle is probably correct. It is that a certain amount of water is necessary to germ life; if this be abstracted, which alcohol can do, the germ will be killed. However, to reach the interior of a germ cell, the law of osmosis—that for its action the interposing membrane, here a cell wall, must be in a moist condition—must be observed. Pure alcohol will neutralize this condition, but a watery alcohol, eighty to ninety-five per cent., fulfils the physical demand, and the germ life is therefore destroyed.

A few minutes since I stated that the two newest and best recommended agents for hand disinfection were alcohol and chlorine. The latter, which I will now take up, has the older reputation as a powerful germicide, dating back to the time of Koch himself, though Kümmel, of Hamburg, was among the first to employ it in practical surgical work, in 1885. This surgeon then stated that the only solutions after whose use no single colony of bacteria developed were those of carbolic acid, five per cent., and, as far as he could then judge, of chlorine water; but that his experiments with the latter were not completed. A year later he[1] reported that after scrubbing the hands and nails with soap and water for three minutes, and then brushing them with equal parts of chlorine water and water, no colonies of germs would be found. Its employment is alluded to but seldom since then in surgical literature, and for my purpose it is unnecessary now to trace its course as an antiseptic.

Some five years ago, becoming more and more unsettled as to the trustworthiness of the sublimate solution, though then used on Fürbringer's plan, I added to my process of hand disinfection a final washing in the officinal chlorine water, which contains two-fifths per cent. of chlorine gas. This notably improved my clinical results, and had a minor but agreeable action in abrogating the usually roughened condition of my hands. A short time thereafter Mr. Rauschenberger, the efficient apothecary of the hospital, suggested the use of a mixture of the household chlorinated lime and crystallized carbonate of sodium, the common washing soda, which, with a little water, would evolve, he said, freshly formed chlorine, and by its other action saponify the skin fats and dissolve to a certain extent the horny skin layer—all of which were decided advantages. This method has well stood the test of time clinically, and it has come into general use for hand disinfection in the hospital with which I am connected, and has also proved itself by repeated culture tests to be among the most reliable of agents for this purpose. Its chemical reaction is a little obscure, but it is virtually a production of the so-called chlorinated soda in a fresh and liquid state, and which is better known by the familiar name of Labarraque's solution. The Pharmacopœia states it to be an aqueous solution of several chlorine compounds of sodium, chiefly NaClO and NaCl, and containing at least 2.6 per cent. by weight of available chlorine.

It is now used in the following way: After a thorough scrubbing with hot running water, green soap, and a brush, aiding the cleansing under and about the nails with a pointed brush, like the end of rattan or soft wood, about a scant tablespoonful, *i.e.*, a large pinch, of the ordinary commercial chloride of lime or bleaching powder is put in the palm of the hand, and on it is placed a crystal of the carbonate of sodium (common washing-soda) about one inch wide and one-half inch thick (or of a size that will permit it to be easily rubbed about like soap). A little water is now added, to make a thick cream, and this is rubbed up and down the palms and hands and arms, until the little rough grains of the chloride of lime disappear or markedly diminish, or until the creamy fluid thickens into a pasty layer. Another ready way to determine when to cease using the soda is to cast it aside when a sense of coolness is felt in the palms, for when the cream is first made a sensation of heat is noticed. The procedure occupies from three to five minutes. Before washing the paste off in sterile water, I prefer to use a sterilized rattan cleaner to rub it under and around the nails. When finally cleansed in the sterile water, the hands will be found smooth and soft and smelling of chlorine. If the odor persists after the operation, neutralization can be had, or before this if any reason exists, by a (sterile) weak one-fifth-per-cent. solution of aqua ammonia. There is seldom any irritation of the skin following this chlorine asepsis. Should such occur, bathing the parts (after the operation) with water and anointing with non-petrolic oil will at once remove it. Depending somewhat on the sensitiveness or thickness of the skin, the procedure can be employed, if required, three or four times a day, without marked irritation. As to the efficacy, consider these figures: Forty-two tests made according to the foregoing method gave forty sterile results, or ninety-five per cent. of successful asepsis.

The advantages for hand disinfection of chlorine and alcohol over any other antiseptic, so far as is now known, are fully apparent, though the testimony of other experimenters is always to be desired in questions of such importance as the one under consideration.

As corroborative of the efficiency of chlorine, I venture to detail a little further the use of chlorine water, which I have already stated was added to the Fürbringer sublimate disinfection by me, in 1892. This addition worked very well clinically, but I was troubled by finding that the chlorine solution varied much in strength, depending on its freshness or the duration of its exposure in a basin. By obtaining the solution, however, directly from the manufacturer, in quart bottles, and by using the same as soon as poured out, this objection was overcome; but these precautions of themselves did not allow the method to be widely recommended. Moreover, though occasional tests with the

[1] Kümmel Archiv f. klin. Chirurg., Bd. xxiii., p. 541. Centralbl. f. Chirurg., 1886, No. 17.

sulphide-of-ammonium solution showed the hands and nails to be free from pyogenic germs (the staphylococcus epidermidis albus being the most difficult to get rid of), yet I was unsettled as to the relative values of the three antiseptics used—to wit, alcohol, sublimate, and chlorine. To obviate the objection made to the sublimate, the hands were, after its use, washed in a solution of carbonate of sodium in lieu of the ammonium sulphide. This avoided the staining that ensues from the latter, and also neutralized the sublimate. By so doing it was then believed that the germs inhibited by the bichloride would be better exposed to the chlorine action, and it would seem from the tests made that this was a fair inference. When tests were resorted to of hand disinfection thus made without the soda washing, one hundred and fourteen in number, only ten failures occurred, which is ninety-one per cent. of successes; but this, please recall, might have been invalidated by the inhibitory action of the sublimate. In fifty-three tests, however, in which the soda washing was done after the use of the sublimate, the result was that in only three tubes were germs found, or that there was ninety-four per cent. of successes. This spoke well for the chlorine addition. The potency of the alcohol as a reliable agent in hand disinfection was not then entertained, it being used merely as a fat extractor; but, when it was pointed out that its efficiency was much greater in bringing about a veritable asepsis, the above method was broken up and the sublimate solution was discarded as unreliable and unnecessary, and the alcohol and chlorine were treated singly to determine their relative values, with the outcome that has already been placed before you.

Bearing additionally on the value of chlorine as a hand disinfectant is the experience of the well-known bacteriological investigator, E. Klein.[1] This observer reports a series of experiments to test the value of another chlorine compound, or, rather, of the same chlorine compound that I have just brought to your notice, for in each set of testings, my own and his, it is the familiar Labarraque's[2] solution, the old solution of the hypochlorite of sodium, that each is working with —made fresh in one instance by the combination of the calcium hypochlorite and the sodium carbonate, and bought ready made in the other. Mr. Klein took the hypochlorite of sodium, which had been made of a ten-per-cent. strength of available chlorine, and, diluting it to one per cent., tested its action on a variety of germs—among which were the proteus vulgaris, staphylococcus aureus, bacillus coli communis, bacillus anthracis, bacillus diphtheriæ, bacillus typhosus, bacillus of swine fever, vibrio of cholera, etc.—with the result that a five-minutes' exposure killed the germs just enumerated. In weaker solutions his results were not so good. I was led by reading his article to try the commercial Labarraque solution, and essayed it first in its pure state, which contains two-fifths of one per cent. available chlorine. It proved in this shape, as was anticipated, too strong for the skin for practical use; but in the nine trials it was employed in this strength, with normally infected hands and a previous washing with soap and water, all the tubes remained germ free. When, however, the solution was diluted to one-tenth strength, in twenty-one trials there were seven failures —*i.e.*, germs showed on cultures. This test was not pursued further, as even in one-tenth strength it caused much skin irritation. Still, in an emergency it could be safely used in half its full strength. It should be further experimented with and reported on as a ready disinfectant.

The conclusions that may fairly be made from this brief *résumé* on the subject of disinfection of the hands, are, therefore:

1. That the solutions of corrosive sublimate are unreliable.

2. That such disinfection is so far best effected and in the order named, by the use of nascent chlorine, alcohol, or potassium permanganate.

3. That the chlorine is satisfactorily evolved by the conjoined use of the moistened commercial chlorinated lime and crystallized sodium carbonate.

4. That of these three procedures, the chlorine treatment is least hurtful to the hands; alcohol the most trying.

In addition to these conclusions, it appears proper to reiterate in a condensed form the results of the various tests that have been made. They are therefore grouped for convenience in the annexed table, to which is joined a condensed description of the various methods of disinfection which have been employed.

TABLE OF TEST CULTURES.

	Total Number of Test Cultures Made.	Contained Germs.	Contained No Germs.	Contained Germs.	Contained No Germs.
1. Bichloride:					
(*a*)	114	10	104	8.7 per cent.	91.3 per cent
(*b*)	53	3	50	6 "	94 "
2. Nascent chlorine:					
(*a*)	42	2	40	5 "	95 "
(*b*)	35	4	31	11.4 "	88.6 "
3. Liq. sodæ chlorinatæ, containing 10 per cent. chlorine	9	0	9		100 "
Containing 1 per cent. chlorine	21	7	14	33⅓ "	66⅔ "
4. Potassium permanganate	31	9	22	30 "	70 "
Alcohol, 95 per cent	24	1	23	4 "	96 "

Methods of Sterilization. — 1. Bichloride: (*a*) Hands and forearms scrubbed with green soap and water; regions under and around nails rubbed with pointed rattan, then scrubbed with 1 to 2,000 alcoholic bichloride for one-half to one minute; scrubbed again in U. S. P.[1] chlorine water; finally soaked in 1 to 1,000 watery solution of bichloride of mercury from three to five minutes, and then in sterile water two minutes.

(*b*) Same as (*a*), except that after soaking in 1 to 1,000 bichloride of mercury the hands are washed with sterile sodium carbonate water (one-half-per-cent. solution) and then soaked in sterile water.

2. Nascent chlorine: (*a*) One or more large crystals of carbonate of sodium are taken in one hand and covered with about a tablespoonful of bleaching powder,[2] and enough water is added to make a thin paste, which at first feels warm and from which fresh chlorine gas comes. This is rubbed for two to three minutes over the hands, nails, and forearms, until a creamy paste is formed, or until the sodic crystals impart a cool sensation, or until the rough grains of the bleaching powder have mostly disappeared, when the hands are washed in sterile water.

(*b*) Same as (*a*), followed by soaking for two minutes in 1 to 1,000 bichloride of mercury. This was done by an error in a number of trials, and hence these results have not been alluded to in the body of the paper.

3. Labarraque's solution of chlorinated soda: (*a*) Ten-per-cent. chlorine (a special strength). Hands and forearms were scrubbed with soap and water, then with Labarraque's solution for one minute.

(*b*)[3] One-per-cent. chlorine strength was made by

[1] "On the Disinfecting Action of Sodium Hypochlorite," by E. Klein. Lancet, Nov. 28, 1896.

[1] Labarraque's solution is made by mixing sodium-carbonate crystals, 150 gm.; chlorinated lime (bleaching powder, hypochlorite of lime), 75 gm.; water (50° C.), 1,000 c.c.

[1] Containing when freshly made 0.4 per cent. of chlorine gas.

[2] Using about twice as much of the soda as of chlorinated lime (bleaching powder).

[3] This solution is about one-half the strength of the commercial Labarraque's solution.

diluting the above with ten parts of water. Hands and forearms were scrubbed with soap and water, then with this solution one minute.

4. Potassium permanganate: Scrub with soap and water; clean nails with wood brush; rub 1 to 16 permanganate solution into hands and arms until they are of a deep mahogany color; immerse in saturated solution of oxalic acid till entirely bleached; rinse with sterile water. In a few instances to further remove any of the disinfectant, baryta water, five per cent. barium hydrate crystals, was used prior to the final washing in sterile water.

5. Alcohol: Hands and forearms scrubbed five minutes with green soap and hot water, and then immersed and scrubbed five minutes in ninety-five-per-cent. alcohol, and finally washed in sterile water.

Control tests were resorted to from time to time in the trial of each antiseptic used. These were made with either freshly obtained pus showing staphylococcus aureus in activity, or with bouillon cultures of the staphylococcus aureus. The following examples are given to demonstrate the methods employed:

Series I.—Control test with disinfection by alcohol: (*a*) Five fingers of the hand were infected with bouillon cultures of staphylococcus pyogenes aureus by rubbing these with a soft rattan brush under and about the roots of nails and on the adjacent skin. Under culture all showed germs, with some few colonies of staphylococcus epidermidis albus.

(*b*) The same fingers were then scrubbed with soap and water three minutes, immersed and scrubbed with ninety-five-per-cent. alcohol three minutes, and then rinsed in sterile water. Result: Four tubes sterile: one showed a few colonies of staphylococcus epidermidis albus.

Series II.—Control tests with nascent chlorine disinfection: (*a*) Five fingers infected as above. Subsequent scrapings placed in agar tubes. Four cultures showed large growth of staphylococcus pyogenes aureus, and one also a few colonies of staphylococcus epidermidis albus.

(*b*) The same five fingers were then scrubbed with soap and water three minutes, scrubbed with nascent chlorine five minutes, and bathed in ammonia, one-fifth-per-cent. solution, three minutes, and finally rinsed in sterile water. Result: Four cultures remained sterile, and one tube showed a colony of a short bacillus and a colony of a large staphylococcus, neither pyogenic.

Series III.—Control test with permanganate-of-potassium disinfection: (*a*) Five fingers infected as in Series I. All cultures therefrom showed an abundant growth of staphylococcus pyogenes aureus.

(*b*) The same fingers were then scrubbed with soap and water three minutes, soaked in permanganate-of-potassium solution, 1 to 16, three minutes, then in oxalic acid saturated solution, until bleached (about five minutes), then in baryta water three minutes. Result: One tube showed no growth whatever: three tubes showed scanty growths of staphylococcus pyogenes aureus; one tube showed a decided growth of staphylococcus pyogenes aureus.

Series IV. is suggestive rather than conclusive. Several times similar control inoculations as have just been exemplified had been resorted to, in which, after intentional infection, when the scrapings were taken from under the nails and about the root of the nails and tested in agar culture tubes, either no germs developed or they showed themselves in unduly few colonies. After some thought the conclusion was arrived at that a sufficient amount of previously used antiseptic material must have remained on the hands of the assistant to inhibit the growth of the germs. This was tested in the following way:

(*a*) Dr. Taylor, the house surgeon, having washed his hands freely with bichloride-of-mercury solution, 1 to 1,000, ten hours later, having in the mean time washed his hands with soap and water, infected all his fingers with staphylococcus pyogenes aureus, and made therefrom test cultures, with the result that in only one out of ten cultures was there any growth found, and that only a single colony of the staphylococcus pyogenes aureus.

(*b*) The same assistant at another time, after two days of hospital work with hands very seldom in bichloride solution, and fifteen hours after the last use of this antiseptic, then tested one of his fingers by dipping it in a sulphide-of-ammonium solution. The skin immediately turned dark brown, and a culture then made from scrapings under and about the nails showed two colonies of long non-pyogenic vibrios.

(*c*) Another finger of the same hand was infected at that time with staphylococcus pyogenes aureus. Scrapings from under and about the nail, taken ten minutes later, developed no germs whatever in the culture tubes.

Not much is known as to the extent to which an animal tissue will retain an antiseptic unchanged within its meshes. Von Zeignek[1] has, however, called attention to the fact that rubber drainage tubes, silk, and catgut, placed in a solution of bichloride, will cause the disappearance of the bichloride in varying lengths of time, sometimes without changing it, sometimes by converting it into calomel; and Braatz[2] more pertinently states that bichloride will adhere to catgut, so that after immersion in a solution of this salt for twenty-four hours, and subsequent washings in frequently changed distilled water, it will give a chemical mercurial reaction for as long as five weeks afterward.

In order to ascertain if this persistent action of antisepsis obtains with substances other than bichloride, a test was made on the hands of another member of the house staff, who ten hours previously had disinfected his hands with nascent chlorine. The five fingers were infected with staphylococcus pyogenes aureus, and cultures were made from the scrapings under and about the nails. No growths, however, resulted.

REMARKS ON SEPTIC PERITONITIS, WITH SPECIAL REFERENCE TO THE USE OF THE ANTISTREPTOCOCCUS SERUM.[3]

By EGBERT H. GRANDIN, M.D.,

NEW YORK.

A few years ago I read a paper before this section, dealing with the question of suppurative peritonitis, giving in outline a report of a number of instances, and drawing the following general deductions as the outcome of personal experience: Instances of local suppurative peritonitis uniformly resulted in recovery, provided free incision and proper drainage were resorted to before general systemic infection had become marked; while instances of general suppurative peritonitis resulted fatally, no matter what the treatment. It is my purpose this evening to amplify the subject somewhat, basing my remarks on my individual experience with suppurative peritonitis (local and general), extending over a period of six years. While a number of the cases from which I draw my deductions occurred in the male sex, I take it that suppurative peritonitis in man differs from that in woman only in the absence of certain etiological factors which the element of sex controls, and again because, when we consider the question of treatment, a very valuable drainage route is present in woman and lacking in

[1] Wien. klin. Woch., October 1, 1896.

[2] Centralbl. f. Bakt. und Parasit., Bd. viii., No. 1, p. 8.

[3] Read before the section on obstetrics and gynæcology, Academy of Medicine, March 25, 1897.

man. Again, I may be able to-night to modify the absolutely hopeless prognosis, stated on the former occasion I addressed this section, as applicable to general suppurative peritonitis.

My records for the past six years reveal forty cases of suppurative peritonitis (local and general) seen in private consulting practice and operated upon by me. This number does not include instances in which I have figured as consultant, but not as operator, and cases of pus collecting low in the pelvis, and therefore accessible by and operated upon by me through the vagina, are excluded. Every one of these forty cases required incision per abdomen, either single or multiple, associated often with counterdrainage into the vagina and through the loin. Were I to include in this analysis instances of so-called pelvic abscess, the number of cases operated upon by me would be increased largely, but with resulting obscurity in the statement of my deductions, because, to judge from my experience, general systemic absorption from these instances is rarely deep, unless operation is postponed to a culpable degree; in other words, the peritoneal cavity (the great absorbent) is rarely markedly involved.

The forty cases I draw my deductions from are differentiated as follows: General suppurative peritonitis, 9 cases; local suppurative peritonitis, 31 cases; total, 40 cases.

The etiological factor was: Suppurative disease of the appendix vermiformis, 31 cases; puerperal infection, 8 cases; ruptured suppurating ovarian cyst, 1 case; total, 40 cases.

All the thirty-one cases of local suppurative peritonitis terminated in recovery. Some were opened in the midline and drained into the vagina; others were opened above Poupart's ligament, or along the line extending from the anterior superior spine to the umbilicus, and drained into the vagina, or by counterincision in the loin. Two cases were reached posteriorly to a line extending from the anterior superior spine to the posterior.

Of the nine subjects of general suppurative peritonitis, eight died and one recovered. In these nine cases multiple incisions, flushing of the peritoneal cavity, and counterdrainage was the treatment in five cases; median incision, flushing of the cavity, and drainage, in three cases; multiple incisions, repeated flushings, multiple drainage, and injection of antistreptococcus serum in one case. This is the single case of general suppurative peritonitis which I have been able to save, and I shall shortly present the essentials to you for consideration.

First, however, I wish to make clear to you what I mean by local suppurative peritonitis and by general suppurative peritonitis.

In cases of local septic peritonitis (or, more properly speaking, purulent peritonitis), the site of infection becomes shut off from the general peritoneal cavity before the infectious toxins lead to the formation of pus. Practically, therefore, we deal with a collection of pus which is extraperitoneal. While systemic absorption occurs, it is from a relatively small absorbent surface, and ordinarily the focus of systemic infection is discovered and treated after the recognized surgical fashion, before sufficient toxæmia has set in to result in deep infection of the system with the well-known sequela of metastasis to organs of the body—such as the liver, spleen, kidneys, brain, etc. The localization of the infectious focus and its early differentiation and surgical treatment constitute the reasons why subjects of local suppurative peritonitis almost invariably recover—in my list of cases, *always*.

In case of general suppurative peritonitis, the infectious toxins invade at once or progressively the general peritoneal cavity. This great lymph sac—as it has been termed—is filled with the germs of infection, and very rapidly these are sucked up by the lymphatics and disseminated throughout the body. According to the virulence of the toxin the systemic infection is rapid or slow, the subjective phenomena are acute or of gradual development, death is relatively sudden or ensues after a number of days or even weeks—in the latter event the clinical picture being that of pyæmia. The invasion of the peritoneal cavity by the toxins, in instances in which death does not speedily ensue, results in the formation of multiple pus cavities—under the liver, the spleen, around the kidneys, around the pelvic organs, etc., giving us a manifold repetition of the condition found under local suppurative peritonitis. From each and every pus pocket the infectious elements are drunk up by the lymphatics and carried to every organ and to every portion of the body. Very quickly, therefore, systemic infection occurs, and even though prompt surgical evacuation of these pus pockets (by multiple incisions) and even though free multiple drainage be established, the infectious foci beyond the reach of the knife lead almost inevitably to death. Our multiple incisions and our multiple drainage result possibly in cleansing the meshes of the great sponge—the peritoneal cavity, but neither the one measure nor the other can reach the toxins in the lymphatics and veins throughout the body.

Until lately, then, I expected death after general purulent peritonitis, and I was not at all ashamed of my mortality rate of one hundred per cent. Lately, however, the outcome of a case which resulted favorably has given me a measure of hope that in the future I may save these cases. And yet my success may only have been one of those rare exceptions which prove the rule, and it is with a mind absolutely devoid of enthusiasm and absolutely free from bias that I give you the essentials of this case, with such comments as I feel justified in making. Without wearying you by entering into elaborate detail, sufficient the following statement:

On February 3, 1897, I saw a lady in consultation, who four days previously had had an attack of what she deemed indigestion. Her family physician had been summoned the day previous to my visit, and had found a slightly swollen abdomen, with but little elevation of temperature or rapidity of pulse. Abdominal pain was sufficient to call for opiates, and, in addition, he ordered saline laxatives. When I saw her the bowels had been freely moved, spontaneous pain was absent, the temperature was about 100° F., the pulse 90, the entire abdomen swollen and exquisitely sensitive to the touch. I agreed in the diagnosis of peritonitis, and gave a presumptive opinion that the etiological factor was perforative appendicitis, deeming an exploratory section safer than expectancy. This opinion was based on the following argument: Two years previously I had operated by median abdominal incision for the removal of a sessile uterine subperitoneal fibroid, and had found the tubes and ovaries normal. I was therefore able to exclude these organs as etiological factors of the peritonitis. The low temperature was consistent with infection of the peritoneal cavity, and the cessation of pain was significant. The relatively slow pulse carried little weight, because I happened to remember that this woman had a normal pulse of about 70.

The advice given was accepted, and that evening I made an incision over the ileo-cæcal region, entering the free peritoneal cavity and giving exit to thin foul pus. The gangrenous perforated appendix—floating free—was ligated and cut off. The coils of intestine which appeared at the incision were congested and bathed in pus. I irrigated gently with hot salt water, and tucked in strips of gauze saturated in pyrozone (three per cent.). I did not deem further exploration

requisite, since there was reasonable doubt as to whether the entire cavity had been infected.

For a few days the temperature ranged between 99° and 100° F., and the pulse from 88 to 100; the bowels moved and the abdominal tenderness began to decrease, and then intense pain over the left iliac region was complained of and the pulse rate began to rise. I made a free incision on the left side, just above Poupart's ligament, and entered a cavity containing over a pint of very foul pus. I washed this cavity out, and then, although it did not pouch in the vagina, I incised to the left of the cervix and established counterdrainage into the vagina by means of a large, thick rubber tube.

During the following day the pulse began to mount to 120, the temperature fluctuating from 99° to 101° F. In the evening the woman's condition was not at all satisfactory, and I determined an area of dulness over the left side of the abdomen, extending above the umbilicus. I sent for a bottle of antistreptococcus serum, and injected twelve and one-half cubic centimetres. At the same time I made a free incision to the left of the umbilicus into the peritoneal cavity, broke up multiple pus pockets, flushed out with a few gallons of salt water, and inserted strips of gauze in every direction.

The next morning twelve and one-half cubic centimetres of the serum were administered, and in the afternoon my second and third incisions were united by a fourth, the abdominal muscles being infiltrated with pus. Thus the left abdomen was laid open, a lower incision draining into the vagina, and through the upper incision multiple drainage of the peritoneal cavity having been established, the entire intervening area being covered with foul grayish slough and the retracted flaps being infiltrated with pus.

By this time I had noted that after the administration of the antitoxin the woman would complain of angina pectoris, requiring the administration of nitrite of amyl; she would be nauseated and have repeated chills, and in a few hours the temperature would drop to 99° F. and the pulse rate to 88. I therefore gave the order that eight cubic centimetres of serum should be injected whenever the temperature rose over 100° F. and the pulse above 90. During the following few days the woman received twenty cubic centimetres more of the serum. A further fact noted was the markedly increased eliminative action of the kidneys after the injection of the serum, the amount of urine passed reaching as high as one hundred ounces.

I will not weary you by detailing the after-treatment. Suffice it that under charcoal dressings the left side of the abdomen gradually cleaned off; the tube into the vagina was removed in about a fortnight, at which time the last strip of gauze (extending downward to the kidney) was removed from the incision to the left of the umbilicus. By means of adhesive straps carrying silkworm-gut strands, I was able gradually to approximate the large flaps, so that at the end of six weeks they were in close apposition. The incision in the ileo-cæcal region closed in about a fortnight. The woman is to-day in perfect health.

What, now, as regards the serum, has this case taught me? I am far from claiming that the woman recovered because of the serum. It is always dangerous to draw deductions of a positive nature from a single case, and, as I look over the literature which my friend, Dr. Gibier, has courteously furnished me, I am all the more loath to be at all dogmatic. I find that the antistreptococcus serum has been used in many cases irrespective of the determination as to whether the case of sepsis was due or not to streptococcus infection. The case I report is fallacious in this respect, for I neglected the very essential point of having the pus examined. Etiologically, I should assume that in my case the bacterium coli played a very prominent part in the infection, and we know that the antistreptococcus serum is powerless against the bacterium coli. If, therefore, the serum entered as a factor in the recovery of my patient, it was because the case was one of mixed infection. Further still, in looking over reported cases, I find recorded instances of puerperal sapræmia which resulted in recovery after the use of the serum *plus* the curette. Now we all know that early curettage of the uterus will ordinarily be followed by recovery, even though the serum is not used; and then again we are told that against staphylococcus infection the antistreptococcus serum is powerless. Possibly the chairman of this section, Dr. Marx, may have come to the conclusion that the serum failed him in the cases he has recorded because either he was dealing with bacterium coli commune or staphylococcus infection, and that therefore he expected from the serum that which it is definitively stated it cannot accomplish.

To return to my case, the antistreptococcus serum appeared to act as follows: Temperature and pulse rate were uniformly lowered after each administration; elimination of waste, infectious products, was favored, as was evidenced by the greatly increased action of the kidneys; pus-production was apparently checked, for, whereas before the use of the serum pus pocket after pus pocket was forming and infectious elements were being rapidly absorbed into the system, not alone after the injection of the serum did pus production cease, but the infiltrated flaps cleaned up far more rapidly than it has been my fortune to see before. I had every reason to anticipate progressive systemic infection and death; I have witnessed rapid throwing off of sepsis and recovery.

In the future I propose to use the serum on the principle that it can do no harm and may do good. Of course, whenever feasible, I shall have the pus examined, for the purpose of determining the causal agent of infection; and if, as I am informed the probability is, a serum can be placed at our disposal effective against the streptococcus, the staphylococcus, and (perhaps) the bacterium coli commune, I am nearly convinced that in the future we may save the relatively small proportion of cases we now lose. Surgical measures, prompt, bold, and radical, will not be displaced, but when they seem futile orrhotherapy may step in to fill the gap, facing which we now are discouraged and powerless.

36 East Fifty-Eighth Street.

A CONTRIBUTION TO THE STUDY OF AMŒBIC DYSENTERY.[1]

By CHARLES E. LOCKWOOD, M.D.,
NEW YORK.

We are realizing more and more every day that the study of the rôle played by the lower organisms in the production of diseased conditions is most important as looking toward the proper diagnosis and treatment of many diseases to which our flesh is heir, and we have only to mention a few to emphasize this statement, such as the actinomyces bovis, bilharzia hæmatobia, ankylostoma duodenale, echinococcus hominis, amœba dysenteriæ; in other words, the trend of scientific investigation is to the discovery of the etiological factors of diseases as leading to more precise diagnosis and treatment. We notice this tendency in the recent writings of those who are making a special study of mental derangements, the influence of physical disorders and autotoxis in their relation to these affections

[1] Read before the New York State Medical Society, at the ninety-first annual meeting, at Albany, January 26, 1897.

being particularly insisted upon, and it is with this conviction that I am led to contribute my experience in the diagnosis and treatment of amœbic dysentery, which it has been proved is caused by the presence of the amœba dysenteriæ in the intestinal canal. Amœba, according to Foster's Encyclopædic Medical Dictionary, is etymologically derived from the Greek word Ἀμοιβή, alternation, and is defined as follows: "A genus of protozoa belonging to the order amœbæa, class rhizopoda, the members of which consist of but slightly differentiated masses of protoplasm characterized by a constant change in form (amœboid movement). Amœba coli, a species discovered by Lösch in great numbers in the dejections and on the mucous membrane of the large intestine of a man affected with dysenteric symptoms, is twenty to thirty-five millimetres in diameter, rounded or pear-shaped, and possesses a few broad pseudopodia, a nucleus, and a few vacuoles. It or a similar species has been observed under like circumstances by other investigators."

A most exhaustive investigation of the amœba and amœbic dysentery has been made by Dr. William T. Councilman and Dr. Henri A. Lafleur, at the Johns Hopkins Hospital in Baltimore, Md., and their report was published in the Johns Hopkins Hospital Reports, vol. ii., Nos. 7, 8, and 9, in December, 1891. According to this report the first account given of the presence of amœbæ in the intestinal contents comes from Lambe in 1859. Lösch was the first author who gave an accurate description of a species of amœbæ which he found in the stools of a dysenteric patient. He claimed for this organism that it was the cause of the disease, and attempted to prove this by injecting stools of the patient containing the amœbæ into the rectum of dogs. The experiments were made on four dogs and were successful in one case.

Next to the paper of Lösch the most important is a series of publications by Kartulis. Investigations were also made by Hlava, Masiutin, and Pfeifer.

Osler was the first in America to find amœbæ. Musser, of Philadelphia, Stengel, Dock, of Galveston, Tex., Cohen, Holloway, and Edebohls, of New York, have reported cases. Drs. Councilman and Lafleur say: "It is probable that in the future we must recognize a number of different organisms as the cause of the various sorts of dysentery;" and they have called the organism which was first described by Lösch under the name of amœba coli, the amœba dysenteriæ. "The name given to it by Lösch is not distinctive, for it seems very probable that there may be a number of species of amœbæ which under certain conditions and in certain localities may inhabit the colon."

In a note, Drs. Councilman and Lafleur say: "An opinion on the sources of the infection must be purely speculative until the morphology of the pathogenic amœba has been fully worked out and its habitat discovered. It seems probable that drinking-water is one if not the chief source of infection."

The case of this disease observed by Dr. George M. Edebohls, of New York, and reported by Dr. John W. Brannan, in 1893, possesses peculiar points of interest, in that "during a period of time extending over six years, five different hepatic abscesses, the result of amœbic dysentery, were diagnosticated and successfully operated upon, the patient finally succumbing to a sixth hepatic abscess, which opened spontaneously and led to death by exhaustion. Post-mortem pathological investigation determined the presence of amœbæ coli in both the large intestine and the liver."

In concluding their report, Drs. Councilman and Lafleur say: "We think it can be said as the result of the work which has been done on the subject:

"1st. Amœbic dysentery is a form of dysentery which etiologically, clinically, and anatomically should be regarded as a distinct disease.

"2d. We would consider that (*a*) the amœba dysenteriæ has been shown to be the causative agent from its constant presence in the stools and in the anatomical lesions and from the inoculation experiments of Kartulis. (*b*) Clinically the disease is characterized by the presence of amœbæ in the stools, which in addition present physical characters different from those seen in the stools of other forms of dysentery as noted above; by a variable onset, course, and duration, of which the special features are periods of intermission alternating with exacerbations; and by a marked tendency to chronicity, with the production of a greater or less degree of anæmia. (*c*) Anatomically the disease is characterized by the production of ulcers in the colon, which generally differ from those found in any other forms of dysentery. The ulceration is produced by infiltration of the submucous tissue and necrosis of the overlying mucous membrane, the ulcer in consequence having the undermined form. Frequently in addition to the ulcers there is infiltration of the submucous tissue without ulceration. In all these lesions, unless complicated by the action of bacteria, there is absence of the products of purulent inflammation.

"3. Abscess of the liver, with or without involvement of the lung, is a frequent complication, much more so than in any other form of dysentery. The involvement of the lung may early follow hepatic involvement and be detected by the occurrence of amœbæ in the sputum before there is evidence of liver abscess. These abscesses differ in their anatomical features from those produced by other causes. The chief difference is found in the absence of purulent inflammation, the abscess being caused by necrosis, softening, and liquefaction of the tissue. In these liver abscesses the amœbæ are not associated with any other organism.

"4th. The disease is widely distributed and is found in most countries in Europe, in most parts of the United States, and in the tropics everywhere.

"5th. This is the form of dysentery which has been commonly called tropical dysentery."

I will now proceed to give the history and details of the case observed by myself: On the 1st of October, 1896, I received a telegram from Boston, asking me to come there as soon as possible to see a patient who, according to the message, was very sick in a hotel in that city, and whom I had treated successfully for diarrhœa while in New York in 1894. I arrived there at eleven in the evening of October 1st, and found my patient, a young man, thirty-two years of age, suffering from a dysenteric affection characterized by frequent, yellowish-brown, watery, offensive stools, accompanied by the discharge of mucus and blood and severe colicky pains. He said he had been under the care of a local physician for six days, and had received a variety of treatment without relief. On questioning him I found that tenesmus was not marked, but he complained of a burning sensation in the rectum and at the anus during and after the passage of fæces. His general appearance was anæmic, and he was much emaciated; his tongue was heavily coated; his temperature taken under the tongue was normal; pulse, 72; respiration, 18. He said he had been spending part of the preceding summer at Old Orchard Beach, in the State of Maine, and while there had drunk some spring water, the taste of which he did not like and which he thinks made his bowels loose; he also stated that he had suffered for a long time from disordered digestion, for which he had undergone much treatment at the hands of different physicians, and that the present attack of dysentery had come on one week before, after he had eaten some ice cream. I prescribed rest in bed, a liquid diet, and an opiate, and after explaining to him the necessity of rest, a prop-

erly regulated diet, good nursing, and a thorough investigation of the etiological factor in the case, which was hardly practicable under the circumstances, I advised that he return to New York. Accordingly the following day he left Boston and went to his home in

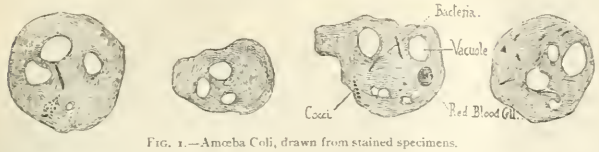

Fig. 1.—Amœba Coli, drawn from stained specimens.

Connecticut and placed himself under the care of his family physician, but, failing to obtain relief, he came to New York on October 7th, and placed himself under my care. He was now very weak and every two or three hours was having watery passages of the same character as before described, accompanied by much pain. I prescribed rest in bed; as a diet, one-half a teacup of arrowroot gruel every two hours, and a powder containing ten grains each of prepared chalk and powdered kino, and one grain of opium every three hours. As this checked the diarrhœa only temporarily, I began to suspect the presence of amœbæ, and on October 9th I took one of the stools to the Carnegie Laboratory, and asked Dr. Edward K. Dunham to examine it, and the next day received the following statement:

"I have carefully examined the fæces brought by you yesterday, and find in the material a considerable number of amœbæ coli. The stool was intensely acid when received, so that none of the amœbæ was found in movement, but from the stained preparations we feel justified in an absolute diagnosis, though we would like to ask you, as a favor to us, kindly to send us a specimen which has been neutralized or rendered faintly alkaline by some alkali immediately on its passage. In such a specimen, if examined early enough, I think we shall be able to demonstrate the amœboid movements. The greater bulk of the stool is made up of pus cells, a few red blood corpuscles are found, a very small amount of predigested food is present, and the stool contains a good many oil globules."

On October 10th and October 11th the patient had six stools each day, although taking every three hours the powder before mentioned, containing one grain of opium, and having secured a stool which had been made alkaline by the addition of one-half a teaspoonful of bicarbonate of sodium directly after its passage, I took it to the Carnegie Laboratory and received the following report: "I have succeeded in finding some very actively motile amœbæ in the stool you left this afternoon. They are characteristic in every respect, showing the vacuoles, pseudopodia, and change in form in a very satisfactory manner, so that there can be no doubt as to their identity."

A careful examination of the patient's urine was made and nothing abnormal found. Realizing now that Dr. Dunham's examinations of the stools had left no doubt as to the nature of the disease, and that active measures should be taken to destroy the amœbæ, I asked Dr. H. M. Biggs to see the case with me, and he advised the use of rectal injections of the bisulphate of quinine in the strength of 1 to 5,000, 1 to 3,000, 1 to 2,500, 1 to 1,500, in three to four pints of water at the temperature of 100° F., preceding their administration by the insertion of a suppository containing one grain of opium, or the giving of an injection of starch with twenty-five drops of laudanum one-half hour before each rectal douche, and that the rectal douches be given three or four times a day; also to give by the mouth two grains of quinine every three or four hours, and six to eight times a day a capsule containing fifteen to thirty minims of castor oil and two and a half grains of salol for its cleansing and antiseptic effect, and one grain of opium every four hours; and as a diet one quart of peptonized milk and the whites of six eggs, with a little salt and water daily. This treatment was begun on the evening of October 12th, a rectal douche being given with a rectal tube of soft rubber, connecting with flexible rubber tubing about four feet in length supplied with a hard-rubber funnel, the patient's hips being elevated by placing the douche pan on folded blankets so as to have the assistance of gravity in securing the penetration of the fluid as deep as possible into the intestinal canal. Directions were also given to the nurse to make the injection slowly and to raise the funnel not more than two feet above the patient's hips, to avoid undue pressure. The time of retention of the douches amounted on the average to five minutes for one-half the quantity injected, and ten minutes for the other half.

On October 13th, I visited the patient and found that he had suffered hardly at all from pain and flatulence since the first douche. The administration of the pills of opium, one grain each, every four hours, was now discontinued, directions being given to administer them only according to indications.

On October 15th, after having used the rectal douches of the solution of bisulphate of quinine, 1 to 5,000, three times a day for two days, I took a stool which had been rendered alkaline by the addition thereto of one-third of a teaspoonful of bicarbonate of sodium to the Carnegie Laboratory for further examination, and received the following report from Dr. Dunham: "I have examined the stool sent over this morning, and find that it still contains the amœbæ, and I was able to study them while still quite motile. The stool contains very much less pus than the former specimens, and, though it is a pretty hard matter to guess at, I think the proportionate number of amœbæ is rather less than before."

I now directed that the strength of the solution of bisulphate of quinine be increased to 1 to 3,000, or ten grains to four pints of water.

On October 16th, after having given three injections of the strength of 1 to 3,000—two on October 15th and one in the morning of October 16th—and having hitherto used the rectal douches in the quantity of only three pints three times a day, I now increased their strength to 1 to 2,500, or thirteen grains of quinine to four pints of water, and ordered their use in the

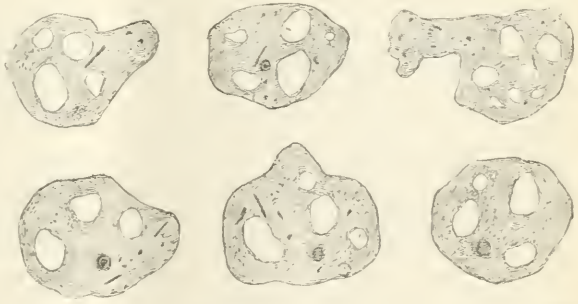

Fig. 2.—Amœba Coli, showing pseudopods and changes in form, drawn from a recent stool which had been rendered alkaline.

full quantity of four pints to be repeated four times a day. The diet during the day, on October 16th, was twenty ounces of arrowroot gruel and sixteen ounces of egg albumen; and the patient was allowed to swallow the juice of a small piece of steak which he chewed.

On October 17th, at 8:30 A.M., a rectal douche, 1 to 2,500, was used, and at 12:45 P.M., 4:30 P.M., and 8:30 P.M., rectal douches of 1 to 1,500 were given —or twenty grains of quinine to four pints of water.

On October 18th, I visited my patient at 11 A.M., and was told by the nurse that he had refused to allow the administration of any more rectal douches, and also was unwilling to take any more castor oil and salol capsules; said he could not digest milk, and insisted on trying meat and solid food in the shape of bread and butter. I objected to such a course, until microscopic examination should show the absence of the amœbæ from the stools, but all to no purpose, as the patient still adhered to his determination. Having explained to him emphatically the risk he was taking, I left him, returning at 5 P.M. on the same day, when I was informed he had eaten a piece of steak and a small piece of bread at 1 P.M., and had had no symptoms of indigestion; that he had had one small loose movement free from mucus at 7:45 A.M., and that he had taken two grains of quinine by the mouth about every three hours during the day, and a pill containing one grain of opium at 3 P.M. At 6:30 P.M. he ate a piece of steak and bread and butter, and suffered no inconvenience except a feeling of weight in the stomach, which was relieved by a small dose of pepsin.

October 19th, the patient was found in good condition, he had a well-formed passage at 9:30 A.M., streaked with blood, which was taken to the Carnegie Laboratory for microscopic examination, the result of which is told in the following letter:

"New York, October 19, 1896.

"Dear Doctor: I have examined the stool sent to the laboratory to-day, and by selecting out the little bits of blood-stained mucus am able to still find fairly active amœbæ; but in the general mass of the fæces they are found only in very small number. I am surprised at the quick and very remarkable improvement in the character of the stools.

"Very truly,

"E. K. Dunham (*per* Brooks)."

I now again urged the patient to resume the taking of the rectal injections, explaining to him the risk he was taking, as the mortality of the disease was reported to be fifty per cent., and he finally agreed to take one rectal douche of the strength of 1 to 1,500 at 6 P.M. His diet on this day consisted of a squab, a piece of beefsteak, arrowroot gruel, and egg albumen.

On October 20th I visited the patient at 11 A.M., and was told that he had refused to take the rectal douche and had discharged the nurse. He was sitting up and said he had had a stool partly liquid and partly solid at 4 A.M., and on close examination was unable to discover any blood or mucus. He said he had eaten beefsteak and bread and butter and had had no symptoms of indigestion. His general appearance was good, and his tongue was clean and red in color.

October 21st, I called on the patient at 10:30 A.M., and was told that he had had no passage from the bowels since 4 A.M. of the preceding day. He had taken a pill of one grain of opium in the early part of the morning.

October 22d, patient had one well-formed passage without blood or mucus or liquid material, which I took to the Carnegie Laboratory, and after it was subjected to a careful microscopic examination I received the following letter:

"New York, October 22, 1896.

"Dear Dr. Lockwood: I have carefully examined the fæces left this morning and fail to find the amœbæ in them; their general character seems very normal indeed. Very truly,

"E. K. Dunham (*per* Brooks)."

I concluded from this report that the amœbæ discovered in the fæces on October 19th were probably inert, having been rendered so by the previous injections of quinine, or by the improved vitality of the patient, and congratulated him on his recovery, advising him, however, as to the possibility of a relapse, and the importance of an occcasional microscopic examination of his stools for one or two months, to ascertain if there was any return of the amœbæ.

The points of interest in this case, it seems to me, are:

1st. The importance of the differentiation of this form of dysentery from the other forms.

2d. The importance of the microscopiçal examination of the fæces in all cases of obstinate diarrhœa, marked by remissions and exacerbations with a notable tendency to chronicity and anæmia, accompanied by the discharge of offensive brownish-yellow liquid stools, associated with the appearance of blood and mucus and colicky pains.

3d. The marked efficiency of rectal douches of bisulphate of quinine in destroying the amœbæ, and the rapidity of the recovery of this patient under their use, their administration in the strength, quantity, and frequency mentioned having sufficed for a cure in this case in five days.

4th. The importance of an early diagnosis in this class of cases looking toward the destruction of the parasite before it has penetrated the submucous tissues, since in that case it is impossible to reach it, and abscess of the liver is liable to occur from migration of the amœbæ.

5th. The danger of relapse after an apparent recovery, Dr. Illoway, of New York, having reported a case in which a fatal recurrence of the disease took place three months after a supposed cure.

6th. The probability of the kinship of the amœba to the germ of intermittent fever, when we consider the efficiency of quinine as a remedy.

7th. The question as to the use of acids as a remedy suggested by the effect of acids upon the vitality of the amœbæ.

8th. Is the long existence of digestive disorders a predisposing factor in the development of a favorable nidus for the amœbæ?

THE COMPARATIVE TREATMENT OF GONORRHŒA WITH PERMANGANATE OF POTASSIUM, PERMANGANATE OF ZINC, FORMALIN, AND NITRATE OF SILVER.

By GEORGE T. HOWLAND, M.D.,

PROFESSOR OF GENITO-URINARY DISEASES AND SYPHILIS IN THE MEDICAL DEPARTMENT OF GEORGETOWN UNIVERSITY, WASHINGTON, D. C.

The medical journals of our own and foreign countries are teeming with articles on the subject under consideration, and it seems as if there could be little said or added to this subject that would be of interest or importance to the medical profession.

The practice of late years has been to cure the disease as quickly as possible, and one reads of remarkable cures produced by some new drug, which upon careful trial does not carry out the written statements in regard to its promptness in effecting a cure. In the experience of the writer it seems a useless waste of time in trying the so-called "specific drugs" for the prompt and rapid cure of gonorrhœa.

In my private and hospital practice, I have used a line of treatment which has given good results. Nothing is here claimed for promptness in cure, although in several instances the cure has been surprising as well as grateful in its promptness. The treatment has been local in all cases, no internal treatment being administered. The diet was adjusted, and nothing but milk and water was allowed as beverages.

The drugs used were permanganate of potassium, permanganate of zinc, formalin, and nitrate of silver in solution. The method of using has been that of irrigation, the amount used being one quart at each sitting. The temperature of the fluid has been 110° F. This applies to all except that of nitrate of silver, of varying strengths, used as an injection with a hand syringe.

As a matter of testing the efficiency of the different drugs above mentioned, each drug was tried on five different patients and the results were noticed.

Permanganate of Potassium.—The solution of this drug used was in the strength of 1 to 500, 1 to 1,000, and 1 to 5,000; temperature, 110° F. The apparatus consisted of an ordinary fountain syringe holding one quart. To the distal end of the syringe was attached a glass meatus nozzle. The patient sat on a chair. The penis was drawn through a hole cut in a piece of rubber cloth about one yard square, which was allowed to fall into a pail placed to catch the fluid as it ran out of the meatus.

Case I.—A. W——, colored, aged twenty-eight, third attack. Discharge appeared three days after exposure. He consulted me two days later. Gonococci present. First irrigation with 1 to 500 at 9 A.M. He complained of pain and soreness, which disappeared before the second irrigation, which was given on the same day at 4 P.M.; strength of solution, 1 to 1,000. He was under observation for eighteen days, and for the first five days he received two irrigations, the morning one being 1 to 500 and the evening 1 to 1,000. The remaining thirteen days he received but one irrigation per day, the strength of the solution being 1 to 5,000. My notes state that on the morning of the fifteenth day after treatment had begun the "morning drop" was observed. The character of the discharge changed to a watery consistency. The permanganate solutions were discontinued, and a solution of boric acid, 1 to 5,000, was used for three days longer, when all evidence of discharge had ceased. He was kept under observation for one week longer, and allowed to eat and drink what he wished. In all, this patient had twenty-six irrigations, extending over a period of eighteen days.

Case II.—W. L——, white, aged thirty, fourth attack. Discharge appeared ten days after exposure. Gonococci present. He received treatment for twenty-one days. He had two irrigations a day for ten days, the morning one being 1 to 500 and the evening 1 to 1,000. The treatment was continued for eleven days longer, and for eight days the strength of the solution was 1 to 5,000 once a day, when the discharge became watery and only a slight gluing of the meatus was noticed in the morning on rising. For three days longer irrigations were continued, with a hot solution of boric acid, 1 to 5,000, when all discharge ceased. He was allowed to resume his ordinary diet, and at the expiration of two weeks his urethra admitted sounds up to 28 French, without the slightest resistance, passed at patient's request. At the end of the third week he was married. He called on me a few days ago, four weeks after his marriage, and reported that he had seen no signs of a discharge. In all, this patient received thirty-one irrigations.

Case III.—G. W——, white, aged eighteen, first attack. Discharge appeared five days after exposure. Gonococci present. Irrigation with 1 to 500 in the morning, and 1 to 1,000 in the evening, for five days; then 1 to 5,000 was used once a day for ten days longer, when the characteristic discharge in the morning was noticed. Irrigation was continued with boric acid, 1 to 5,000, for three days longer, when the discharge disappeared. He was told to call at the end of a week if no discharge appeared. He called at the end of the week and reported no discharge. The patient was under treatment for eighteen days, and received in all twenty-three irrigations.

Case IV.—G. C——, colored, aged nineteen, first attack. Discharge appeared on the second day after exposure. Saw the patient on the following day. Gonococci present. Morning and evening irrigations of 1 to 500 and 1 to 1,000, respectively, were used for four days. Then 1 to 5,000 was used once a day for twelve days, when the discharge was noticed only in the morning, and then the hot boric solution, 1 to 5,000, was used once a day for three days, when all discharge disappeared. He called at the end of ten days and reported no discharge. This patient was under treatment for nineteen days, and received in all twenty-three irrigations.

Case V.—C. L——, white, aged twenty, second attack. Discharge appeared three days after exposure. Saw the patient on the next day. Gonococci present. Morning and evening irrigations of 1 to 500 and 1 to 1,000, respectively, were used for five days, when the solution of 1 to 5,000 was used once daily for eight days, when the discharge became only a slight gluing of the meatus in the morning. Then the boric acid, 1 to 5,000, was used once daily for three days, when the discharge disappeared. At the end of two weeks he reported no discharge. This patient was under treatment for sixteen days and received in all twenty-one irrigations.

Permanganate of Zinc.—The following five cases were treated with permanganate of zinc. The strength was 1 to 500, 1 to 1,000, and 1 to 5,000. Irrigation was the method employed, given with the apparatus described by Dr. Valentine, of New York; temperature, 110° F.

Case I.—W. W. P——, white, aged eighteen, first attack. Discharge appeared three days after exposure. I saw him on the fourth day; gonococci were present in the discharge. Morning and evening irrigations of 1 to 500 and 1 to 1,000, respectively, were used for eight days, when the solution of 1 to 5,000 daily was used for fifteen days. On the twelfth day the discharge ceased, but the irrigations were continued for three days longer. He reported at the end of seven days no discharge. The patient was under observation for twenty-three days. In all, he received thirty-one irrigations.

Case II.—C. McC——, white, aged twenty-six, second attack. Discharge appeared five days after exposure. I saw the patient on the same day. Gonococci present. The morning and evening irrigations of 1 to 500 and 1 to 1,000, respectively, were continued for ten days, when the discharge warranted the use of the weaker solution, 1 to 5,000, which was used daily for fifteen days. On the thirteenth day only a slight gluing of the meatus was noticed on rising in the morning. The irrigations were continued for two days longer, when the discharge disappeared. This patient was under treatment for twenty-five days and in all he received twenty irrigations.

Case III.—J. T. F——, white, aged thirty-one, fifth attack. Discharge appeared three days after exposure. He consulted me on the next day. Gonococci present. The morning and evening irrigations were continued for seven days, when the solution of 1 to 5,000 was used daily for sixteen days. On the fourteenth day the discharge ceased, but the treatment was continued for two days longer. He reported no discharge at the

end of a week. This patient was under treatment for twenty-three days. In all he received thirty irrigations.

Case IV.—J. B——, white, aged twenty-eight, first attack. He contracted gonorrhoea six weeks previous, had been under treatment, and was discharged as cured two weeks ago, but he noticed after treatment had been stopped that there was a slight discharge in the meatus in the morning, but this gave him no concern, as his "friend," who had had gonorrhoea five or six times, told him that this would soon pass away. Two days before he consulted me he had been "out with the boys," although he denied having had intercourse. The discharge appeared on the following morning more profuse than at any time since he had stopped treatment. On the second morning it was still more profuse, and on voiding urine there was considerable smarting. Discharge could be expressed from the urethra. Examination with the microscope showed the gonococci, and on examining the urethra with the electric-light urethroscope a spot was revealed about one millimetre from the posterior margin of the fossa navicularis. The two daily irrigations of 1 to 500 and 1 to 1,000 were commenced and continued for twelve days, when the solution of 1 to 5,000 was used daily for sixteen days. On the thirteenth day the discharge was slight and was noticed only on rising. The treatment was continued for three days longer, when the discharge entirely ceased. He was under observation for fourteen days longer, visiting me twice a week. At the end of the first week he had resumed his regular mode of diet. He was under treatment for twenty-eight days and received in all forty irrigations.

Case V.—J. H. McG——, white, aged seventeen, first attack. He was brought to me by his father nine days after exposure, the discharge having appeared two days previous. He told his father on the eighth day, and on the following day they consulted me. Gonococci present. The morning and evening irrigations of 1 to 500 and 1 to 1,000 were used for six days, when the character of the discharge changed so that the milder solution, 1 to 5,000 was used daily for eighteen days. On the fifteenth day it ceased, but the irrigations were continued for three days longer. He was under observation for two weeks longer. No discharge appeared. I saw the patient a month later; he complained of no trouble. The patient was under treatment for twenty-four days, and received in all thirty irrigations.

Formalin.—In the cases treated by this drug, the following strengths were used: one per cent., or one ounce of formalin to two and one-half pints of water; one-half per cent., or one ounce of formalin to five pints of water; one-fourth per cent., or one ounce to ten pints of water.

Case I.—J. G——, white, aged twenty-one, first attack. Discharge appeared on the third day after exposure. Consulted me on the following day. Gonococci present. Morning and evening irrigations were commenced at once of one per cent. and of one-half per cent., respectively, and were continued for five days, when the discharge was modified so that we could use the weaker solution, one-fourth per cent., daily for seven days, when all discharge ceased and at the expiration of one week it had not returned. This patient was under treatment for twelve days, and received in all seventeen irrigations.

Case II.—C. A——, white, aged thirty-three, second attack. Discharge appeared eleven days after exposure. He consulted me on the thirteenth day. Gonococci present. Morning and evening irrigations of one per cent. and one-half per cent., respectively, were used for ten days. Then one-fourth per cent. was used daily for twelve days, when the discharge disappeared. He visited me ten days later and reported no discharge. This patient was under treatment for twenty-two days, and received in all thirty-two irrigations.

Case III.—M. McH——, white, aged twenty-eight, second attack. Discharge appeared two days after exposure. He was seen on the same day. Gonococci present. His occupation was such that he could be treated but once a day. The one-per-cent. solution was used for fourteen days; then the one-half-per-cent. solution was used for fifteen days longer, when the discharge ceased. He was seen ten days after treatment had been stopped and reported no return of the discharge. This patient was under treatment for twenty-nine days, and received in all twenty-nine irrigations.

Case IV.—A. B. T——, colored, aged twenty-nine, third attack. Discharge appeared two days after exposure. Gonococci present. Morning and evening irrigations of one-per-cent. and one-half-per-cent. solutions were used twice a day for ten days. Then the one-fourth-per-cent. solution was used for thirteen days, when the discharge ceased. At the end of two weeks he reported absence of all discharge. This patient was under treatment for twenty-three days, and in all received thirty-three irrigations.

Case V.—G. C——, white, aged twenty-five, second attack. Discharge appeared seven days after exposure. He consulted me on the third day, or ten days after contracting the disease. Gonococci present. The morning and evening irrigations were commenced at once and were employed for nine days, the strength of the solutions being one per cent. and one-half per cent., when the weaker solution, one-fourth per cent., was commenced and used daily for fourteen days, when the discharge disappeared. I did not see the patient again for three weeks. He reported no discharge in the interval. This patient was under treatment for twenty-three days, and received in all thirty-two irrigations.

Nitrate of Silver.—This drug was used in the following manner. The solutions were made by adding two grains of the drug to one ounce of water for the first, and then increasing by two grains to each ounce. The numbers ranged from two to twenty-four. The method of introduction was by the hand syringe, one drachm being thrown into the urethra and retained there for five minutes. The injections were given every other day, increasing two grains, at each sitting. The patient was instructed how to use the hand syringe and was told to inject the following prescription on the intervening day, viz.:

℞ Zinci sulph. ..... gr. i.
Hydrastis. ..... ʒ ij.
Aquæ dest. ..... ʒ iij.
M. S. Use night and morning after urinating.

Case I.—W. T. B——, white, aged twenty-one, first attack. Discharge appeared three days after exposure. He consulted me the same day. Gonococci present. Injection No. 2 was given and the above prescription, to be used as directed. On the second day the nitrate-of-silver injection was increased by two grains. This treatment was continued for eight days, when the silver nitrate was stopped and the prescription alone used, for one week longer, when the discharge ceased. This patient was treated by silver nitrate for eight days, receiving eight injections, and of the prescription fifteen injections.

Case II.—J. G——, white, aged thirty-six, second attack. Discharge appeared three days after exposure. Consultation on the same day. Gonococci present. This patient on alternating days received as high as twenty grains of the silver to the ounce. The prescription was employed for one week longer, when the discharge ceased. He received ten injections of the silver solution, and of the prescription seventeen injections.

Case III.—L. G. C——, white, aged nineteen, first attack. Discharge appeared on the second day after exposure. I saw him on the third day. Gonococci present. This case was treated as the above cases, the injections being carried up to No. 10, or ten grains to the ounce, in combination with the prescription on the day of interval. That is, five injections of silver nitrate were given, when the discharge was so slight that the nitrate was stopped, and the prescription used for seven days longer, when all discharge ceased. The patient was seen two weeks later and reported no discharge.

Case IV.—J. J——, white, aged eighteen, first attack. Discharge appeared on second day, and on the same day he consulted me. Gonococci present. The injections of silver nitrate were carried up to No. 8, or eight grains to the ounce, when it was stopped, and the prescription was continued for one week longer, and then stopped. The patient was seen two weeks later, and reported no discharge. The injections of the silver solution were used only four times, and the prescription eleven times.

Case V.—D. Q——, white, aged thirty-six, second attack. Discharge appeared on the fifth day. He consulted me on the next day. Gonococci present. The silver nitrate was carried up to No. 10, or ten grains to the ounce, when the discharge was so lessened that the prescription was used but for five days, when it ceased. He was seen seven days later, and reported no discharge. He received but five injections of silver nitrate, and of the prescription ten. Two weeks later he called on me to have some sounds passed, as he thought he had a stricture. Sounds up to 28 French were passed without any difficulty.

From the foregoing cases, I think that I am justified in stating that in the drugs used we have a treatment that comes very close to being the ideal one. It is such a marked improvement over the methods that were in vogue not more than ten years ago that its simplicity and efficiency must commend it to all who have much of this work to do. In all these cases the disease was confined to the anterior urethra and acute in form. In chronic cases, the seat of disease being in the posterior urethra, I use intravesical irrigations of permanganate of potassium and zinc, in the strength of 1 to 5,000, and also the silver salt, introduced by the Ultzmann-Keyes syringe, and also the hot boric-acid solution, 1 to 5,000. These cases require a longer time to cure, but the method is equally efficacious. Of the different drugs used I find that the least irritating of all are permanganate of zinc and formalin. The other two drugs need some milder solution to complete the cure.

The main point that I wish to lay stress upon in the treatment of gonorrhœa by this method is the doing away with the nauseating internal treatment: or, as a patient of mine so happily puts it: "It is a pleasure to have 'clap' in these days, as one does not have to take those vile teaspoonful doses of medicine, which always upset my stomach."

315 Vermont Avenue.

The Best Method of Removing Large Calculi from the Bladder.—Dr. Freyer (*Lancet*, December 12, 1896) says that he has no hesitation in pronouncing Bigelow's method the safest and best for calculi of all sizes in patients of all kinds and conditions; that he would lay down as an absolute rule that no patient should be subjected to a cutting operation until after trial litholapaxy is found not to be feasible. When this method is not practicable, Dr. Freyer considers that calculi, up to about three ounces in the adult and a corresponding size in the child, are best removed by perineal lithotomy; beyond that suprapubically.

Progress of Medical Science.

Antipneumococcus Serum. — Washbourn (*British Medical Journal*, February 27, 1897, p. 510) gives an account of the immunization of a pony to pneumococcus infection, with the description of a method for estimating the protective power of the serum, and reports two cases of pneumonia treated with the serum. The pony first used was injected with broth cultivations of the pneumococcus which had been heated to 60° C. for an hour and subsequently with living cultivations. After being under treatment for nine months, the animal was suddenly seized with intestinal obstruction and died after a few days' illness. A second pony was injected with broth cultivations heated to 60° C. for an hour, then with living agar cultures, and finally with living broth cultivations. The injections were made into the subcutaneous tissues of the shoulder. During the process of immunization an abscess containing streptococci formed near the foreleg from some accidental cause and ruptured. The animal became very ill and it was feared that it would die, but as a result of great care the abscess gradually healed and the pony convalesced. Five months after the last injection the animal was bled and the serum was found to possess marked protective properties. The cultivations used were always made from the blood of an infected rabbit and were employed after from twelve to eighteen hours' incubation at 37.5° C. The inoculations were followed by local swelling, pyrexia, malaise, and loss of appetite. To preserve the virulence of the pneumococci, the surface of the agar medium was streaked with sterile rabbit's blood. In all of the experiments a loopful of the cultivation was made into an emulsion with a known quantity of sterile broth. By dilution any fraction of the contents of the loop could be obtained. Cultivations twenty-four hours old were always used. The virulence of the micro-organisms which were obtained from the blood of a mouse dead after inoculation with the sputum from a case of pneumonia, was established by nine passages through rabbits, with intermediate cultivation on blood agar. In testing the serum, measured quantities were mixed with ten times the minimum fatal dose of the cultivation and the mixture was immediately injected into the peritoneal cavity of a rabbit. The smallest quantity of serum that protects the animal under these circumstances is called a unit. Sera from horses not immunized to the pneumococcus and from other animals were tested and found to be without protective influence. Experiment showed that the serum from immunized animals possesses the power of protecting animals against infection when injected either at the same time or subsequent to inoculation. It could not be determined whether or not it possessed also antitoxic powers, as no satisfactory toxin has thus far been obtained from cultivations of the pneumococcus. Of the two cases of pneumonia treated with the serum, the one occurred in a stevedore, twenty-nine years old, in whom six hundred and sixty units were injected on the eighth and ninth days. The injection was followed in each instance by a fall of temperature and on the day after the second injection the crisis occurred. Inasmuch as this was on the ninth day, it is difficult to say whether or not the result was due to the treatment. The attack was a fairly severe one, but the pulse was good before the serum treatment was adopted. The second case was one of bilateral pneumonia in a law writer, of intemperate habits, twenty-five years old. An injection of six hundred and sixty units of serum was made on the third, fourth, and fifth days. The attack was a severe one, with a good deal of delirium and signs of dilatation of the heart. The serum appeared to exert

a beneficial effect. In both cases an urticarial rash was observed, similar to the rashes occurring after injections of antitoxic and antistreptococcic sera.

Traumatic Rupture of the Liver.—In the *Australasian Medical Gazette*, Dr. Someren reports a fatal case of hepatic rupture: A woman, aged thirty-six years, married, nullipara, was seated on a cart, next the driver, passing along a main road, when the driver found it needful to turn off the siding on to the road, and in doing so the cart was tilted suddenly and acutely to the side of the driver. The woman fell against the driver, who, seated on the extreme edge and unprepared, jumped off, thus removing the expected support from the woman, who then rolled helplessly and in a heap off the dray, and fell on her head, while her body lay just across the wheel track. By this time the dray had got on to the crown of the metalled road, and here the wheel went over her abdomen, she lying on her back. She was taken up and put on the dray, supported in a half-reclining position. A little blood issued from her mouth. She made the remark, "I feel faint," and lapsed into unconsciousness. The dray came back to a hotel, about three hundred yards from the scene of the tragedy, and she was taken out and put on a bed, and there she expired very shortly after. It should be mentioned that she seemed at first not to be breathing at all, but just before getting to the hotel she began to breathe better and more perceptibly. The doctor arrived upon the scene very soon after her death, which occurred within half an hour of the accident. There was a very superficial abrasion upon the forehead, just at the parting of the hair, and this was the only mark upon her person anywhere. Pallor was great, but not strikingly marked. From the history he judged that death was the result of rupture of an abdominal viscus, probably the spleen or the liver; but the statement that blood had issued from the mouth made him doubt whether the fall on the head might not have produced some rupture of a cerebral vessel. The coroner ordered a post-mortem. The doctor proceeded to open the abdomen first of all, prepossessed by the idea that he would discover there the cause of death. Beginning with the median incision, he then made a transverse one from the xiphoid cartilage to the right flank, and reflected the flap downward and outward, laying bare the right hypochondrium, and in the course of this came across a blood extravasation in the adipose tissue, which was most abundant, in some parts as much as an inch in depth. This extravasation was just at the edge of the cartilage of the ninth right rib. Further reflection disclosed a fracture of the ninth right rib, the posterior portion overriding the anterior. Opening the peritoneum, he came upon an enormous effusion of blood, and, raising the thoracic wall, the liver could be seen with several rents in Glisson's capsule, which seemed to proceed radially from posteriorly, principally in the right lobe. Passing his hand around the liver between it and the ribs, he ascertained that the overridden fragment of the fractured rib did not penetrate internally at all. Then pushing the hands over the convex surface of the liver backward, he came upon a pulpy mass of liver, merely held together by fibrous shreds. Almost the whole posterior border of the liver was thus macerated, including the whole right lobe and a great part of the left. The capsule was stripped off in all directions. The mass of blood was enormous. No other organ whatever was in the least injured, though all, naturally, were exsanguine. The concave surface of the liver was comparatively uninjured anteriorly and inferiorly; all the vessels, afferent and efferent, being intact. Approximately speaking, quite half the liver was broken up, and apparently this was accomplished by the posterior portion being crushed against the angle of the ribs and spinal column, and there macerated by the force applied anteriorly and from the right side externally. How a viscus with the characteristics of the liver could be thus extensively, deeply, and thoroughly injured, under the shelter of the ribs, by a force roughly calculated as equal to half a ton, and yet not the slightest abrasion or mark be present upon the skin even to indicate that such an external force had been applied, seems a problem in vital dynamics which calls for solution. The woman had on loose but fairly good corsets, her other clothing being of a very flimsy, slight character.

Fracture and Dislocation of the Second Cervical Vertebra as a Result of Muscular Effort.—Lobingier (*Colorado Medical Journal*, February, 1897, p. 41) has reported the case of a machinist, twenty-one years old, and an experienced athlete, who in the performance of some feat on the horizontal bar fell limp and lifeless. In "snapping under," instead of easily emerging on the opposite side of the bar and finishing in a graceful vault, the man's head fell upon his chest and his body forward, semi-prone. No sound was heard by the observers, as of the snapping of bones or ligaments, and it was insisted that his head struck nothing in passing beneath the bar. Examination of the cervical spine failed to disclose any deformity. The reflexes were abolished and only feeble cardiac activity persisted. The vertebral column was adjusted so as to prevent injury from a possible fracture, and artificial respiration was instituted and maintained for an hour. Respiratory and cardiac stimulants besides were given hypodermically and repeated at frequent intervals. Electricity was employed and inhalation of oxygen practised. Despite every effort the patient could not be resuscitated and death took place. Upon post-mortem examination no cerebral lesion was discovered, but the second cervical vertebra was found to be thrown forward and to the right on its articular bearings for fully an eighth of an inch. The anterior common spinal ligament was ruptured through its three layers. The lip of both the second and third vertebræ was broken off irregularly along the line of junction. On the right side this fracture extended into the inferior articular facet of the second vertebra. On removing the spinous process of the second vertebra the cord was found soft and degenerated for a distance of an inch. The greatest change in the cord existed at the point opposite the articulation of the second with the third segment of the spine, showing that the pressure of the odontoid process on the cord would not fully account for the softening. The neck of the patient measured sixteen inches in circumference and was intensely muscular, with an unusually large amount of ligamentous and aponeurotic tissue. It is believed that the lesions found resulted from violent contraction of the left posterior group of cervical muscles, with simultaneous and co-ordinate relaxation of the right anterior group, allowing the head to drop violently backward and to the left.

The Pathology and the Surgery of Intussusception.—In the Hunterian lectures delivered recently before the Royal College of Surgeons of England, d'Arcy Power (*British Medical Journal*, February 13, 1897, p. 381) stated that the evidence derived from anatomic, physiologic, pathologic, and clinical data renders it legitimate to assert that spontaneous ileocæcal intussusceptions occur when the colon is considerably larger than the ileum, and is so unduly movable that it readily allows itself to become invaginated when once the process has been begun. This variety of intussusception is essentially an affection of child-

hood, and such an undue increase in the width of the colon implies either a congenital abnormality or an unduly rapid growth, for at birth the diameter of the large intestine is practically the same as that of the ileum. Such a rapid increase in the width of the large intestine may, perhaps, in some instances render the ileo-cæcal valve less competent to guard the end of the ileum, because the valve is not capable of very rapid growth if it is to be firm, but this is probably a factor of very rare and subordinate importance. Though anatomic peculiarities are important factors in the production of intussusception, the physiologic factors are no less important, for they apply in all probability to every form of spontaneous invagination, whether it is of the enteric variety, the ileo-cæcal, or the colic. The physiologic factor is much less easy to specify than the anatomic, for it is almost certainly an individual peculiarity. It may be stated broadly, however, that, as regards the ileo-cæcal portion of the intestine, the increased mobility, coupled with the unduly rapid growth in the width of the large intestine, is probably associated with increased and irregular peristaltic movements of the large intestine. Everyone who has had much experience in watching children must have noticed how subject they are to an irregular twitching of the muscles, and how greatly such inco-ordinate movements vary in different children and in different families. They are most common at the instant when the child drops off to sleep and during the act of awakening. They occur both in the voluntary and the involuntary muscles, and are due, as physiologists think, to a contraction of the interfibrillar sarcoplasm, while the ordinary tetanus and twitch are caused by an additional shortening of the contractile fibres. This theory explains why the symptoms of intussusception so often appear at the instant when a child awakens; why it is that boys rather than girls, and the most active and the best-grown children, are attacked as often as those who suffer from chronic inflammatory affections of the alimentary canal. The muscular system in the active and well-grown is undergoing its greatest development, and its sarcoplasm is in as unstable a condition as in the puny in whom the attacks of enteritis have unduly heightened the irritability of the intestinal muscle, and have thus led to the irregular twitchings which, together with suitable anatomic conditions, may form the starting-point of spontaneous intussusception. The cause of intussusception is obscure, but clinical evidence shows that it may be produced mechanically, though the spontaneous form is the more common. Among such mechanical causes are direct injury to the belly, sudden and violent muscular efforts, gymnastic movements, jolting or dandling, paroxysmal coughing as in whooping-cough; or it may even be the reward of greediness, as in the cases of some men who were suddenly seized with symptoms of intussusception shortly after eating a quantity of cherries—stones and all. It is indeed no matter of surprise that such causes should produce an intussusception, for any of them might lead to a sudden and limited constriction of the intestine associated with an active peristaltic movement of a neighboring portion sufficient to draw the receiving layer of the gut over the contracted portion, which then becomes the apex of the intussusceptum. As soon as the intussusception has been started, the anatomic peculiarities again become of paramount importance, for they determine the character of the intussusception. In the ileo-cæcal forms, a wide colon, with few and simple ileo-colic folds, devoid of lymphatic glands, will allow the intussusception to run a chronic course, even though the amount of bowel invagination is very great. Complex fossæ, with numerous glands at the ileo-colic angle and prolongations of mesentery along the end of the ileum, will no doubt so far steady the ileum as to render its intussusception less likely; but if it should occur, the additional amount of tissue invaginated will render the impaction so peculiarly tight that, if gangrene is not produced at once, early adhesions will be formed and the intussusception will soon become irreducible.

An Afebrile Case of Scarlatina with Diphtheria.—Varnali (*Archiv für Kinderheilkunde*, B. xxi., H. v., vi., p. 358) has reported the case of a strong, well developed boy, three and a half years old, without hereditary predisposition, who was seized with a mild attack of scarlet fever. Two days later a small patch of pseudo-membrane was observed upon the left tonsil, and the adjacent submaxillary and cervical glands became enlarged. The child was somewhat somnolent and without appetite. The temperature was normal and remained so throughout the whole course of the illness, except on one day toward the close of the attack, when in conjunction with constipation it rose to 100.4° F., to decline again after the action of a dose of calomel. The false membrane extended to the soft palate, the uvula, the pharynx, and finally to the nares. On the fifth day the child was convalescent, although the membrane in the throat did not disappear entirely until several days afterward. In the course of another week desquamation had taken place, while œdema of the eyelids set in and albumin appeared in the urine.

Wandering Spleen.—Dr. J. Bland Sutton (*The British Medical Journal*, January 16th) says that splenectomy for wandering spleen is both a justifiable and highly successful operation, the rate of recovery being equal in skilled hands to that of ovariotomy. It has occurred to many that it would be desirable to secure the spleen in the left hypochondrium by means similar to those adopted for movable kidney. Dr. Pouwer has endeavored to carry this out in two instances, but from results it is evident that the patients ran greater risks and were confined to bed longer than though he had removed their spleens. The dangers from a wandering spleen are: (1) Rupture of the stomach or duodenum. (2) Intestinal obstruction. (3) Abscess of spleen. (4) Rupture of the spleen.

Breech Presentation with Extended Legs.—Drs. W. S. A. Griffith and A. W. W. Lea read a paper on this subject before the London Obstetrical Society on January 6th. Seventeen cases were briefly described and the following conclusions arrived at: 1. The extension of the legs in incomplete breech presentations may be either primary or secondary. 2. In the primary variety, which occurs before labor has begun, the breech engages readily in the brim, and the diagnosis can be made. 3. In the secondary variety the extension occurs during labor. This form is more frequent than the primary. 4. This complication is more frequent in primiparæ, namely, seventy per cent. of the cases. 5. The prognosis, with regard to the child, is not worse than is that in pelvic presentations in general. 6. Cephalic version is advantageous before labor is advanced. It is not usually possible in the primary, but may be so in the secondary variety. 7. Most cases are delivered naturally. 8. Prophylactic reduction of the leg is required only in exceptional cases. 9. It is probable that flexion of the leg on the thigh is preferable to bringing down the leg into the vagina. 10. If aid is required in the lower part of the pelvis, the soft fillet will usually effect delivery.

The Influence of Influenza on the Female Organism.—Gabrielle v. Engle (*Wiener med. Presse*, Nos. 43 and 44, 1896) writes that of the four clinical forms—the purely febrile, the nervous, the catarrhal, and the

gastric—women suffer most from the first two. Pre-existent disease, such as endometritis, congestive or infectious, shows exacerbations, while metrorrhagia and intermenstrual discharge are frequent. The author cites two instances in which a latent perimetritis was aggravated and followed by a fatal result in one case. Hemorrhage was noted in one instance in which the appendages had been removed and menstruation had ceased. In anæmic and chlorotic girls in whom menstruation had been irregular, the flow became regular after an attack of influenza. In some cases of premature climacteric there was a resumption of the menstrual function in consequence of influenza. Pregnancy and labor were often gravely affected, and many abortions and premature labors occurred during the recent epidemics. The advent of influenza in the puerperium simulated puerperal fever, and interfered with the secretion of milk. Statistics of birth, as shown by the author, indicate that the power of conception was lessened by the epidemic. Diminution of the number of births was due also to weakening of the male element in reproduction. The author concludes that influenza is an infectious disease having a serious effect on the genital organs, and capable even of leading to grave national and economic questions.

Spurious Constipation.—Dulberg (*British Medical Journal*, March 13, 1897, p. 653) reports three cases of what he designates as spurious constipation. No action of the bowels would take place unless aperients were used and no sooner was the use of these discontinued than constipation again set in. One of the cases occurred in a medical man, who had always had a regular movement of the bowels until he suffered from a sharp attack of diarrhœa, following which he was compelled to use an aperient to overcome his constipation. Upon the conception that the use of the aperient resulted in the expulsion from the bowel of any residuum of fæces within it, the saline was withdrawn, and the lower bowel resumed its expulsive function as soon as it contained a sufficient amount of residual fæces.

Syringomyelia in the Sequence of Traumatism.—Huismans (*Deutsche medicinische Wochenschrift*, February 18, p. 122) reports a case in which symptoms of syringomyelia appeared in the sequence of a traumatism, although it is not made clear that the spinal lesion may not have antedated the injury, which transformed a latent into an active process. The patient, employed as a driver, slipped and fell upon the left elbow. Upon the same day, toward night, he fell a second time, now striking the right shoulder. In the course of seventeen days he was able to resume his work, although shooting pains persisted in the right arm and the right shoulder. After the lapse of a year he ceased work entirely, the right shoulder having become greatly increased in size. In walking, the right leg was dragged somewhat. Gait and station were rather unsteady. Lancinating pains had never been present, although twitching of the legs took place in the recumbent posture. The knee jerk was increased upon the left and entirely absent, even with reinforcement, on the right. Percussion of the right patellar tendon resulted in adduction of the left thigh. The abdominal reflexes were feeble: the cremasteric reflex could not be elicited on either side; ankle clonus was not present. Slight nystagmus existed, but there was no difficulty in speech. The action of the sphincters was maintained, although there was some weakness of the detrusor urinæ. The circumference of the right shoulder measured forty-four centimetres, that of the left thirty-five centimetres. On the right side the deltoid, the infraspinatus, and the supraspinatus were in a state of pseudo-hypertrophy, while the muscles of the left shoulder were atrophied. The right deltoid was greatly enlarged and, together with other muscles, exhibited fibrillary contraction during rest. In raising the right arm some of the muscular bundles of the deltoid contracted, with the development of deep fissures, indicating that some of the fibres were atrophic and replaced by fat. The strength of the right arm was out of proportion to the size of the member. The small muscles of the hand had shown signs of atrophy for only a short time, and this was more marked on the left than on the right. The right lower extremity was smaller and weaker than the left. The muscular development of the right side of the face was better than that of the left side, and the folds and lines were better marked on the former than on the latter. The mobility of the face appeared, however, to be symmetric. The left half of the tongue was considerably smaller than the right, and the organ, when protruded, deviated toward the left. On movement of the shoulder-joints a coarse crepitus was appreciable. The osseous portions of the second joint of the right second finger were enlarged. There was kyphoscoliosis of the dorsal and lumbar regions of the spine. The faradic irritability of the muscles was generally preserved, but was lost in the median portion of the right infraspinatus; the galvanic irritability was markedly altered. Common sensibility was preserved, but the sense of pain was impaired, especially over the affected muscles. The temperature sense was profoundly affected, cold and heat being generally not distinguished. Heart and lungs were normal and the urine was free from albumin and sugar.

The Effects of Bicycle Riding on the Perineum.—Dr. M. E. Aldhuy (*Gazette Hebdomadaire de Médecine et de Chirurgie*, December 6, 1896) deals with the lesions of the perineum produced by the bicycle saddle, the action of the external genital organs, and acute traumatisms of the perineum and their etiology. He considers that the injuries to the perineum caused by the bicycle are of a very serious nature. Lesions such as cutaneous erythema, abscesses, hæmatoma, and a more or less profound anæsthesia caused by repeated pressure have been observed, as well as certain functional troubles, such as retention of urine in men and undue frequency of urination in women. Chronic inflammation of the canal and certain inflammatory complications may be produced or aggravatd by the bicycle. Occasionally the venous arrest due to compression of the perineum causes erection, but more often the perineal massage of the saddle produces temporary impotence. With regard to genital excitation there has been much exaggeration. Such results might be due to wrong posture or defective saddle. The most serious accidents are traumatic in nature and are produced by jolting over uneven roads or by falling on the rear wheel or framework. These falls need not be serious; sometimes there is only a slight tear of the urethra which heals rapidly. The author cites a case in which a fall on the wheel caused an enormous hæmatoma of the perineum and of the scrotum. The bloody tumor increased and the patient presented symptoms of internal hemorrhage; the integrity of the canal was determined by means of a catheter. An incision was made, which revealed a tear of the transverse artery of the perineum. A ligature was applied which arrested the hemorrhage. The urethra is sometimes completely ruptured, and in such case all the complications which usually follow a rupture of the canal may be observed. As the section of the urethra is here ordinarily very distinct, suture of the ends may be followed by union of the first intention. Poucet observed an instance in which seven years after complete rupture of the perineal urethra the patient did not show the least symptoms of stricture.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, April 3, 1897.

IS MALARIA A WATER-BORNE DISEASE?

THE belief that water may contain the plasmodium of malaria and that infection may occur from the alimentary canal through water or the juices of succulent fruits grown in malarious regions is widespread. One fact of considerable weight in support of this theory is that it is firmly held by very many physicians practising in parts of this country where malaria is most rife, and who presumably therefore have had the best opportunity to study the disease and its mode of propagation. But this argument is negatived by another fact, that Italian physicians do not as a rule regard the water-borne theory of malaria as tenable.

In an interesting review of the pros and cons of this controversy, published in the *Bulletin of the Johns Hopkins Hospital* for March, 1897, Dr. Rupert Norton, of Washington, analyzes the reports of malaria on shipboard and in garrisons, upon which the partisans of the water-borne theory rest their case for the most part, and finds them far from conclusive, for no case, he says, among all those recorded as water-borne, gives a positive finding of the malarial parasite in the blood, certainly one of the most necessary proofs to show that the patient really had malaria. Furthermore, the symptoms in a large number of the reported cases supposed to be of malarial infection were not those of malaria, but of typhoid fever or of autotoxæmia of intestinal origin.

Dr. Norton rightly contends also that the only incontestable experimental demonstration of this theory is wanting. "To prove that malaria is water-borne in a given case demands conditions of a peculiar character: first the patient must never have had malaria, and must live and have lived in a district supposedly quite free of malaria; after drinking a certain supply of water and allowing for the proper period of incubation, the malarial parasite must be found in the patient's blood. In the mean time no soil should have been turned up in the patient's neighborhood, he should not have exposed himself to infection in any way, as by travelling into a malarious country, sleeping out at night, etc. Even if all these demands could be satisfactorily met, there would at the present time still be the proof lacking that the malarial parasite lived in the water." It may be found in water, in which case the probability of infection through drinking-water would be enhanced; but we may, on the other hand, find that it does not live in water for any length of time, and then the possibility of infection through this medium would be greatly diminished.

Another argument against the water-borne theory is that cases of malarial fever do not occur in groups in which the disease can be traced to single sources of infection, such as a special supply of water or milk; at least, the relation has never been so directly demonstrated as in the case of typhoid fever or cholera, for example.

As a result of his probing of the evidence that exists for and against the water-borne theory, Dr. Norton concludes that "though we cannot say that malaria is never contracted from drinking-water, yet the best proof is against this common belief. It is impossible to demonstrate that something never occurs, and we must be satisfied with showing that all the evidence that has been so far collected to confirm the water-borne theory is not of sufficiently exact quality to carry much weight."

The burden of proof distinctly lies on those who endeavor to show that the commonly accepted theory is incorrect, and we think most impartial critics will agree with the author of this paper that the necessary conditions of such proof have not yet been fulfilled.

THE LATEST EFFORT OF THE "REFRACTING" OPTICIAN.

AFTER a number of defeats of similar measures, a bill has been introduced into the senate of the State of New York, known as senate bill No. 1,001, which is designed to give the so-called "refracting" optician the legal right to prescribe for errors of refraction, after he shall have passed an examination in optics. It is to be hoped that this measure will meet with the fate of its predecessors. That no bill having such a scope ought to become a law must be patent to every physician, and will upon very little reflection and study become evident to every legislator. A great many objections can justly be urged against legislation of this sort. But the one great objection which stands out boldly and makes it a fatal mistake to confer such powers upon any but medical practitioners is the fact that such abuse would result in serious jeopardy to the safety and health of the public.

The most elementary knowledge of the eye and its functions teaches us that, in administering to this organ, we cannot separate it from the rest of the body. It is subject to the same laws, to the same diseases, and to the same risks. It is a well-known fact that the most skilful and successful oculists are those who have, previous to making a special study of the eye, laid a good and broad foundation with a comprehensive knowledge of general medicine. So much has been written concerning the connection of the organ of vision with the rest of the body that it seems superfluous to do more than allude to the existence of this important relationship. Many conditions causing an interference with sight and hence referred to the eyes are dependent upon some abnormal state of the

system, for which glasses will not only give no relief but may do harm. Certain grave diseases are recognized by an examination of the background of the eye; and the oculist is thus enabled to call the patient's attention to the existence of some disease of the body or one of its organs, refer him to the family practitioner, and enable him to avail himself of treatment at a time when interference may be the means of saving or prolonging life.

These facts are so indisputable and so important that it is somewhat surprising that proposed legislation of the sort alluded to can receive any attention at all. The protection of the public demands that he who prescribes for the eye in any form, whether through glasses or in any other manner, should possess the necessary medical knowledge. And since such necessary training includes proper education in general medicine preliminary to a special experience in ophthalmology, no one but a physician can prescribe glasses without exposing the public to the risks of error and other dangers.

The optician has his sphere, and it is a very useful one. He has it in his power to become skilful and eminent in his profession—that of grinding lenses according to the formulæ of oculists, and mounting these in frames so that they will not only have the desired optical effect, but will also correspond to the varying physical peculiarities presented by the faces of different patients. For the satisfactory execution of his work there is need of considerable knowledge of optics and mechanics. Let him perfect himself in these directions; and let him give up the idea that any one who is not a physician can ever prescribe glasses either properly or with safety to the patient.

A PROPOSED SUBSTITUTE FOR INTUBATION.

Despite the brilliant results of intubation of the larynx in diphtheritic obstruction of the glottis, there are certain disadvantages connected with its practical execution which prevent it from being accepted as an ideally perfect procedure, and which must continually stimulate to search after improved methods.

Dr. Charles Douglas suggests, in *Pediatrics* of March 15, 1897, a substitute for intubation which he describes as catheterization or swabbing of the larynx. During a severe epidemic in Detroit, in 1880, in the course of which he saw many cases of laryngeal diphtheria which he was unable to relieve by tracheotomy because of opposition from the parents, he hit upon the expedient of dislodging the membrane by means of a catheter passed into the larynx. A gum catheter was passed through the rima glottidis, and moved rapidly up and down, so as to loosen the pseudomembrane. The result was temporary relief in almost every case, but the dyspnœa almost invariably returned in the course of a few hours by reason of the reformation of the membrane, and so the operation was finally abandoned.

The introduction of the antitoxin treatment of diphtheria has emboldened Dr. Douglas to return to his former method, since, owing to the speedy control of the disease by the curative serum, the danger of a reformation of the false membrane is practically removed. He reports the case of a little patient treated in this way with gratifying success.

The membrane, three inches long, was quickly ejected after one treatment with the catheter. The patient was completely relieved of all distress and made a recovery without any tendency to returning dyspnœa. The free use of antitoxin, the writer believed, gave protection against a return.

We do not believe, and no more does the author of this method, that it will supersede tracheotomy or intubation, but it would seem to be a simple operation, and might be worthy of a trial, especially as failure would result in but slight delay, and intubation or tracheotomy could still be carried out if necessary.

The advantages which the writer in *Pediatrics* claims for his procedure are that: "(1) Any physician can generally meet this difficulty, even though he never intubated or performed tracheotomy; (2) The necessary instruments can be obtained at any drug store for a few cents; (3) No care or attention is required afterward, as in tracheotomy or intubation; (4) The patient has no difficulty in feeding, as in intubation; (5) It carries no horrors to the parents, is quickly done, and when successfully accomplished gives complete relief." So far, Dr. Douglas says, no harm has resulted from this treatment in his hands.

News of the Week.

Concerning Medical Journals.—A newspaper catalogue recently published by an advertising house in this city contains some interesting points in relation to the medical journals published in North America. According to this most recent authority, the medical profession of this country supports, directly or indirectly, 275 periodicals, of which 10 are issued weekly, 11 semimonthly, 225 monthly, 6 bimonthly, and 23 quarterly, with a combined yearly circulation of 16,017,200 copies. Estimating that there are in round numbers 120,000 medical men of all schools north of the Gulf of Mexico, of whom probably not over 80,000 subscribe to a medical journal of any kind, this vast amount of literature seems like an enormous burden to carry. It will occur to every one, however, that a good proportion of this immense circulation is made up of a very large number of periodicals which are published openly or covertly for advertising purposes by manufacturers of pharmaceutical preparations, and is practically gratuitous. One very serious result of this undoubted plethora of periodical medical literature is the encouragement it offers to laxity in the prompt payment of subscriptions to such journals as are published primarily in the interests of the medical profession, and which depend directly upon the payment of their subscription bills for their existence.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C., March 27, 1897. Changes

in the medical corps of the navy for the week ending March 27, 1897. March 22d.—Assistant Surgeon G. D. Costigan detached from naval laboratory and department of instruction and ordered to the *Vermont*. March 23d.—Surgeon C. A. Siegfried detached from the *Massachusetts* and ordered to the torpedo station; Surgeon S. H. Dickson detached from the *Texas* and ordered to the *Massachusetts;* Surgeon W. R. DuBose detached from the *Terror*, April 6th, and ordered to the *Texas;* Surgeon Oliver Diehl detached from the Philadelphia naval hospital, April 5th, and ordered to the *Terror*, April 6th; Surgeon T. C. Craig placed on the retired list, from March 12th; Passed Assistant Surgeon R. M. Kennedy detached from the Norfolk naval hospital, April 3d, and ordered to the Philadelphia naval hospital. March 26th.—Assistant Surgeon D. E. Carpenter detached from the *Franklin* and ordered to the *Raleigh*.

The Prevention of Tuberculosis in New York.—The health department of New York has taken the step of declaring pulmonary tuberculosis to be an "infectious and communicable disease dangerous to the public health." It has also ordained that notification of each case of the disease coming under the notice of medical practitioners in the city shall be made within a week of its first coming to the knowledge of the practitioners, and that public and private institutions and dispensaries shall also notify all cases heard of. . . . The medical members of the department regard it as quite feasible, even in face of the present estimate of 20,000 tuberculous citizens in New York, to restrict tuberculosis within the narrowest bounds, and eventually perhaps almost to exterminate it. Future comparative records from New York will prove to be of interest in this connection. To our way of thinking the whole scheme is Utopian.—*The Lancet.*

Regulating the Dispensary Abuse.—Upon the initiative of the New York Medical Society for Advancing the Practice of Medicine, a bill has been introduced into the legislature of this State by Senator Sullivan, to regulate the business of carrying on dispensaries, with a view to confine the benefits of dispensaries to the really poor and to prevent the despoiling of the private practitioner of his patients. After defining a dispensary as "a place, established by any person, persons, or corporation, for the practice of medicine and surgery, and to give medical and surgical aid or treatment gratuitously to poor persons who are unable to pay therefor," the bill provides that no person shall apply for such treatment in any dispensary, nor shall any person, persons, or corporation conducting such dispensary give treatment or medical aid to any person unless such person shall be a poor person and unable to pay for medical treatment. It also does away with the ten-cent and dollar-a-month abominations, by providing that all persons entitled to treatment shall receive such treatment free from charge, and shall also be supplied with the necessary medicines or appliances; and furthermore, that no one conducting a dispensary shall receive any pay whatever, directly or indirectly, for treatment, medicines, or appliances that may be required. All those applying for dispensary relief shall produce a certificate from the owner of the house where they reside, from the police captain of their district, from their alderman, or from any charity organization, to the effect that they are poor and unable to pay for medical treatment. The application for or obtaining dispensary relief, except in the case of an emergency, or the giving of a certificate when the person is not known to be poor, is to be made a misdemeanor. The act further provides for the appointment of a board for the supervision of dispensaries in the city of New York, and makes neglect to conform to the rules and regulations of this board by any of the dispensary authorities punishable by fine or imprisonment, or both. The closing section of this act provides that "the husband and wife shall be jointly and severally liable to pay for professional services of a physician rendered to them, or either of them, or any member of their family, and the joint or several property of the husband and wife shall be liable to levy and sale under an execution upon such judgment, except such property as may by law be exempt from levy and sale under an execution." At a meeting of the joint committee of the Medical Society of the County of New York, of the New York County Medical Association, of the Eastern Medical Society, and of the New York Medical Society for Advancing the Practice of Medicine, a committee was appointed, consisting of Drs. Washburn, Wiggins, McGowan, Stewart, M. J. Burstein, L. Cherurg, Gottheil, Landesmann, Tarler, and Lewinsky, to attend the hearing on this bill on March 30th.

"The Medical Buckeye Flyer" is the name of a special train which will start from somewhere in the West, the circular of information sent us does not say where, and will proceed to Philadelphia *via* Columbus, Ohio. In Columbus the train will be boarded by many of the military surgeons, who hold their annual meeting in that city shortly before the meeting of the American Medical Association. Any members of this association who desire to go by the "Medical Buckeye Flyer" may obtain further information by addressing Dr. R. Harvey Reed, at Columbus, Ohio.

Philadelphia County Medical Society.—A stated meeting of the Philadelphia County Medical Society was held on March 24th, the president, Dr. James Tyson, in the chair. Dr. Albert E. Roussel read a report of "Four Cases of Glandular Fever in the Same Family, One in an Adult." Dr. H. A. Hare exhibited a man presenting great gouty deformity in the fingers of both hands. Treatment with dry hot air was followed at first by evidences of a widespread gouty storm, although subsequently marked improvement took place, the tissues apparently becoming softer and normal color of the surface being restored. A skiagraph showed only the bony deformity, but gave no indication of the deposits of sodium urate. Dr. Hare also read a paper entitled "The Value of Intravenous Injections in the Treatment of Toxæmia, chiefly Uræmic and Diabetic." He exhibited the apparatus employed, and detailed cases under his care that had been thus treated.

The Virginia State Board of Health.—Governor O'Ferrall has appointed the following members of the State board of health to serve for four years, from March 15, 1897: Drs Rawley W. Martin, Lynchburg; Paulus A. Irving, Hugh M. Taylor, and Landon B. Edwards, Richmond Vernon G. Culpeper, Portsmouth; John H. Neff, Harrisonburg; and Lewis E. Harvie, Danville.

A Medical-Practice Law.—The New Hampshire legislature has passed a law regulating the licensing and registration of medical practitioners. It provides that after September 1, 1897, no person shall have the right to the use of the title M.D., or Dr., or to advertise himself as a physician or surgeon, unless previously registered, or unless licensed and registered as required by this act. The examinations are to be conducted by three separate boards of medical examiners, of five members each, representing the New Hampshire Medical Society, the New Hampshire Homœopathic Medical Society, and the New Hampshire Eclectic Medical Society. The boards are to be appointed by the governor and council from a list of ten nominees submitted by each society for that purpose. The superintendent of public instruction is to be the regent of the board of medical examiners. Applicants examined and licensed by other State examining boards registered by the regent as maintaining standards not lower than those of the New Hampshire board, and applicants who matriculate in a New Hampshire medical school before January 1, 1898, and who receive the degree M.D. January 1, 1903, may, without further examination, receive an indorsement of their licenses or diplomas conferring all rights and privileges of a license issued after examination. Every person who is in the practice of medicine or surgery in the State prior to the passage of the act is entitled to registration on payment of a fee of $1.

An Ordinance Concerning Expectoration, which has been adopted by the board of health of the village of Saranac Lake, N. Y., reads as follows: "All persons who expectorate in consequence of any disease of the air passages (lungs, throat, mouth, and nose), are positively forbidden to spit or discharge such expectorated matter upon the floor of any house, store, church, schoolhouse, hall, or upon any sidewalk, or in any dooryard, or other place where such matter may be the means of communicating disease to other persons. Any person who shall violate the first section of this ordinance shall be liable to a penalty not exceeding $5 for the first offence, nor more than $25 for a subsequent offence, which penalty shall be imposed by and at the discretion of the board of health." Dr. McClellan, president of the board, writes that the moral support which the board has received in favor of its action is such that it has not been found necessary to impose a single penalty. A first notice usually brings the offender to a proper sense of duty, with the assurance of future good behavior.

The Hospital Saturday and Sunday Collection.—At a meeting of the distributing committee of this association in the city hall a few days ago, the treasurer reported that the collections for the year amounted to $61,500, or $2,500 more than the collections of last year. Of this sum $8,200 was set aside for special purposes, according to the wishes of the givers, and $3,300 was reserved for expenses. The sum of $50,000 was then allotted to the different hospitals in various amounts from $250 to $5,000, the only two receiving the latter amount being the Montefiore Home and Mt. Sinai Hospital. The German Hospital came next with $3,125.27, and St. Luke's was fourth with $3,045.29.

Dr. Douglass Ewell, of this city, died of pneumonia on March 22d. He was a graduate of the College of Physicians and Surgeons, and subsequently studied in Europe.

The Meeting of the American Medical Association.—Dr. H. A. Hare, chairman of the committee of arrangements, writes, calling the attention of those who are thinking of going to the Philadelphia meeting of the American Medical Association, that there will be at the same time a large mercantile convention, which will to a certain extent utilize a considerable number of the rooms in the various hotels. For this reason it is advisable that physicians who intend to be present at the meeting should write at once to one of the hotels engaging such rooms as they desire. If any of the visiting physicians prefer to take rooms at some good boarding-house, the chairman of the committee on reception and accommodation, Dr. G. E. de Schweinitz, 1,401 Locust Street, will be glad to send the addresses of good boarding-houses to those who will communicate with him, signifying their desire.

Antitoxin—American Pediatric Society.—The collective investigation (report) will be held open until April 10th, in order to secure returns of all cases beginning before April 1st. The committee desires to express its appreciation of the trouble and pains the profession has been willing to take in this matter. The blanks have been more understandingly made out than for the first report.

Orrhotherapy in Paris.—A hospital is to be built in Paris, near the Institut Pasteur, in which patients suffering from infectious diseases will be received and treated orrhotherapeutically. The money for the purchase of the site has been given by Madame Lebaudy.

Eastern Medical Society.—The second annual banquet and ball of the Eastern Medical Society was held on Thursday, March 25th, at the Lexington Avenue Opera House, the object being to promote social intercourse, and if possible to secure means for the development of a library. The following gentlemen responded to the toasts of the evening: Dr. Louis Fischer, Dr. H. B. Adler, Dr. William S. Gottheil, Dr. Carl Beck, Dr. Browd, Dr. Farler, Dr. H. J. Garrigues, Dr. Jur. Rudolph Loreck, Dr. G. W. Teschner, Dr. B. Gordon, Dr. L. W. Zwisohn, Dr. Ludwig Wein. Dancing followed the banquet and the arrangement committee's labor was amply rewarded by a financial success.

Boston Infants' Hospital.—At the opening of the new lecture room of the Boston Infants' Hospital, on March 17th, Dr. Northrup, professor of children's diseases in the Bellevue Medical College of New York, addressed by invitation the students of the Harvard Medical School on tuberculosis in children. The lecture was illustrated by lantern slides. The lecture was a great success and excited much interest.

Sixty Millions of Francs is the sum which a French paper has stated as the amount which the physicians of New York derive from their combined efforts.

Mütter Lectureship of the College of Physicians of Philadelphia.—The next course of ten lectures instituted by the late Prof. Thomas Dent Mütter, M.D., LL.D., on "Some Point or Points in Surgical Pathology," will be delivered in the winter of 1899–1900, before the College of Physicians of Philadelphia. The compensation is $600. The appointment is open to the profession at large. Applications stating in full subjects of proposed lectures must be made before October 1, 1897, to committee on Mütter Museum, John H. Brinton, M.D., chairman, northeast corner of Thirteenth and Locust streets, Philadelphia, Pa.

Japan is said to contain a greater number of thermal springs than any other country on the globe.

The Physicians of Bermuda propose to celebrate the Queen's "diamond jubilee" by the creation of a fund for the payment of two trained nurses to serve in the cottage hospital. These nurses can be obtained in London, on a three years' agreement, at the rate of £60 each per annum, and board at the hospital when unemployed. A very generous offer has already been made respecting the travelling expenses of these nurses from London, and there are reasonable grounds for hoping they will be sent out free as far as the hospital funds are concerned.

Non-Combatants and Bravery.—The line officers in the British army and navy snub the surgeons and sneer at them as "non-combatants," yet in the recent expedition to Benin the only officer killed was Surgeon Fyfe of the navy, who was shot while succoring a wounded comrade. A telegram announcing his death, which was read in Parliament, called him a naval sergeant.

A Memorial to Two Heroes.—A stained-glass window has recently been placed in St. Peter's Church, in Fernandina, Fla., by Dr. J. B. Upham, in commemoration of Drs. Welford and Herndon, who died there of yellow fever in 1877. When the epidemic was at its height and the sick were left to die unaided, because of sheer physical inability of the resident physicians to attend to so many, two physicians from Virginia came to the town and devoted themselves freely to the care of the sick. They did brave work, but were themselves numbered among the later victims of the disease. The inscription on the window which commemorates this sacrifice, runs as follows: "Francis Preston Welford, M.D., James Carmichael Herndon, M.D. Born in Fredericksburg, Va. Died, in the faithful discharge of their duty, at Fernandina, Fla., October, 1877. To whose memory, in grateful recognition of their noble lives and heroic death, this window is dedicated by a New England member of that profession which they so much honored and adorned."

Pilgrimages and Epidemics.—A resolution has been adopted by the delegates to the International Sanitary Conference, calling upon all governments to prohibit, or at least restrict, pilgrimages by every practical means in their power. The British delegate stated that the government of India had already decided to prohibit this year's pilgrimage to Mecca entirely. The member from Holland stated that pilgrims from Java were required to be provided with a personal certificate, stamped at departure and on return. The Persian delegate announced the prohibition of pilgrimages to Mesopotamia, and the representative of Egypt said that as far as it was possible pilgrims from Egypt would be prevented from going to Mecca this year. Russia reported that not only all Mohammedan but Christian pilgrimages had been prohibited. Turkey alone of all the powers maintained that pilgrimage was one of the cardinal points of the Mohammedan religion, and that therefore no pilgrim could or would be prevented from going to Mecca. As Turkey is the power that rules Europe to-day, the pilgrimages to Mecca will doubtless continue, plague or no plague.

The Eighth International Pharmaceutical Congress will be held in Brussels, from August 14th to 21st. In addition to questions of general pharmacy and applied chemistry, matters connected with hygiene, public health, and sanitary legislation will be discussed. The special attention of the members of the congress will be called to the subject of drinking-water. The preparation of antitoxic serums and of various organic substances which have recently been introduced into therapeutics will also be debated.

National Confederation of State Medical Examining and Licensing Boards.—The seventh annual meeting of this confederation will be held in the small banquet hall of the Hotel Walton, at Philadelphia, Monday, May 31, 1897, at 10 A.M. The following programme has been arranged: Address of welcome, by Dr. A. H. Hulshizer, of the Pennsylvania State board of medical examiners; response by Vice-President Reed; report of the committee on minimum standard of requirements; discussion and action thereon; report of the secretary and treasurer; annual address of the president; some practical experience with and results of the medical law of Pennsylvania, by Dr. William S. Foster, Pittsburg; the need for exact information as to the equipment, methods, and requirements of our medical schools, by Dr. J. N. McCormack, Bowling Green, Ky.; address by Prof. J. W. Holland, M.D., dean of Jefferson Medical College, Philadelphia; paper; miscellaneous business; election of officers; adjournment. The objects of the confederation are to consider questions pertaining to State control in medicine and to compare methods in vogue

in the several States, the collection and dissemination of information relating to medical education, and to consider propositions that have for their purpose advancement of the standards in the United States. A cordial invitation is extended to all members and exmembers of State medical examining boards, and to physicians, sanitarians, and educators who are friendly to the objects named, to attend the meeting and participate in its proceedings. Dr. William Warren Potter, of Buffalo, is the president, and Dr. A. Walter Suiter, of Herkimer, N. Y., secretary.

The Founder of the Red Cross Society.—Mr. J. Henri Dunant has been living in great poverty in Appenzell, Switzerland, and appeals have from time to time been made to philanthropists for contributions to remove this blot upon the name of a great philanthropic organization. His wants have at last been relieved through the charity of the dowager-empress of Russia, who has sent him a gift of $750 and has promised an annuity of $500.

Snuff Adulterated with Lead.—An unusual source of lead-poisoning was brought to light recently by the arrest of a firm of wholesale tobacconists. A case of plumbism, the origin of which was obscure, was finally traced to the use of snuff bought of the accused. An analysis of the snuff revealed, it is said, about six per cent. of bichromate of lead. There is a provision in the statute against selling adulterated or unwholesome food, but as snuff did not come under this provision it was found necessary to proceed against the firm for obtaining two cents, the price of the snuff, upon false pretences.

Payment of Life Insurance for Accidents.—It is said that in Austria a person who loses both his hands in an accident can claim the whole of his life-insurance money, on the ground that he has lost the means of maintaining himself. For the loss of the right hand he can collect from seventy to eighty per cent. of the total.

Dr. William Pepper, professor of the principles and practice of medicine in the University of Pennsylvania, and formerly provost, celebrated, on March 12th, the thirty-third anniversary of his entrance into the medical profession, by entertaining the present and some of the former members of the Pepper Medical Society, together with a number of the professors and younger instructors in the medical department of the university.

The Missouri State Medical Association. — This association will meet in St. Louis, May 18th, 19th, and 20th. All the first, the second, and the third day until noon will be devoted to the scientific programme. On the evening of the first day the association will as a body attend a session of the Illinois Society in East St. Louis. On the evening of the second day the Illinois Society will attend as a body a session of the Missouri Association, after which there will be a banquet and reception. On the third day both bodies will adjourn and join in a steamboat excursion on the river.

Fined for a Wrong Diagnosis.—A French physician has recently been punished by the courts for an error in diagnosis. He was called as an expert witness for the prosecution in the trial of a woman, who had been arrested on a charge of infanticide, and declared that she presented all the signs of recent delivery. Two days later, however, she was delivered of a child, and she therefore prosecuted the too confident expert, who was found guilty and fined 1,000 francs.

College of Physicians of Philadelphia.—A stated meeting of the section on gynæcology of the College of Physicians of Philadelphia was held on March 18th, Dr. John M. Baldy occupying the chair. A discussion on the use of antistreptococcic serum in the treatment of septic conditions was the subject of discussion. Dr. B. C. Hirst reported cases in which the serum had been used, but without good results, and he advised great circumspection in the selection of cases and the employment only of reliable serum. Dr. R. C. Norris reported a case of puerperal septicæmia successfully treated with the serum. The results in this case were striking and comparable to those observed from the use of antidiphtheritic serum in suitable cases. The case was complicated by an attack of recurrent erysipelas, upon which the serum appeared to exert little if any influence. Dr. G. E. Shoemaker reported a case of septicæmia following criminal abortion, in which injections of antistreptococcic serum were employed without avail. Post-mortem examination disclosed a conspicuous absence of inflammatory lesions and of evidences of septic infection. Dr. E. P. Davis reported a case of puerperal septic infection following self-induced abortion, in which marvellous results followed injections of antistreptococcic serum. In another case, seen at a late stage, a fatal result followed, but the integrity of the serum could not be vouched for. Dr. J. M. Baldy reported a case of acute puerperal lymphangitis and phlebitis treated with the serum, in which a fatal result followed in such a fashion as to lead to the belief that death was due to the treatment. Dr. J. B. Shober made a statistical report of cases recorded in the *British Medical Journal* and *The Lancet* for 1896, covering a total of twenty-one cases, with seventeen recoveries and four deaths.

A meeting of the section on general medicine of the College of Physicians was held on March 15th, the president, Dr. J. C. Wilson, in the chair. Dr. Wilson exhibited a case of horseshoe kidney. Dr. S. S. Kneass demonstrated Widal's method of serum diagnosis of typhoid fever. Dr. H. A. Hare made some remarks on the employment of capsicum for the purpose of stimulating the absorption of medicaments given by the mouth.

The Providence (R. I.) Medical Association, at its annual meeting on March 1st, adopted a resolution to place upon record its official opinion that the proper use of antitoxin is the best means we have of antagonizing the virus of diphtheria, and that the method of diagnosis of diphtheria by the bacteriological examination of swabbings from the parts suspected of being infected is the most accurate of all methods in use.

Plague Serum Ready.—It is stated that a hundred horses have been treated with the plague virus and immunized, so as to furnish a large supply of the pest antitoxin should the disease be brought to France.

Small-Pox in New York.—Several cases of small-pox have been discovered in this city, the first case being found in the New York Hospital in the person of a man who was taken to the hospital from a lodging-house in Park Row.

A Minister of Health.—It has been suggested in England that a minister of health should be appointed and that his department should include the following: 1, The registration department; 2, the local government department; 3, the factory and workshop department; 4, the analytical and chemical department; 5, the veterinary department; 6, the public works and prisons departments; and 7, the lunacy department. It has also been proposed to take the office entirely out of politics, by providing that the minister of health should be appointed for life—that is, he should not go out of office with the government, and that he should have a seat in Parliament. *The Lancet*, in commenting upon these suggestions, does not regard the latter as practicable. The health officer should, it thinks, enter Parliament by the ordinary method and have cabinet rank. Without being a cabinet minister, it says, his opportunities would be enormously diminished, and it is obvious he could not occupy this position if he were not in political sympathy with the government in office.

To Arrest the Hospital Abuse.—The agitation against hospital and dispensary abuse in Baltimore has resulted in the formation of a society to attempt to stop the abuse. In spite of this, however, St. Joseph's Hospital, which has recently received a large legacy, has opened a new dispensary; and the Hebrew Hospital has opened one directly opposite the Johns Hopkins Hospital. These two dispensaries have injured the practice of East Baltimore physicians.

Obituary.

ERNST BRAND, M.D.,

STETTIN, GERMANY.

On the 8th of March this distinguished physician and hygienist departed this life in Stettin, Germany. Dr. Brand was the pioneer of a systematic bath treatment of typhoid fever, by which the mortality of the disease has undoubtedly been reduced to a small percentage.

Being early in his medical career convinced of the value of water as a remedial agent in acute and chronic disease, Dr. Brand had an opportunity to apply the bath treatment in typhoid fever on a large scale among the French prisoners stationed in Stettin during the Franco-Prussian war. In common with others, Dr. Brand had found the expectant plan, which awaits the advent of grave or threatening symptoms and treats them as they arise, unsatisfactory and often fatal when least expected. He became persuaded that the physician who followed this method was, as it were, subject to the whims or accidents of the disease and had no positive basis for his treatment, because he rarely succeeded in successfully combating perforation, hemorrhage, and other complications after they had once been established. To prevent these was Brand's chief solicitude, and he devised a method of bathing which aimed to enhance the integrity of the nervous system and endow the organism with a resisting capacity that would enable it to meet the inroads of the toxæmia, which so undermines the vital power and enfeebles the heart that hypostasis in large organs and necrosis at the point of intestinal ulceration are permitted to ensue.

The method of Brand was an innovation upon all other methods of bathing, the chief and only aim of which was reduction of temperature. Brand was the first to recognize and teach that the true *rationale* of the cold bath in typhoid rested upon the shock and consequent reactive stimulus to the cutaneous nerves and vessels, which, being conveyed to the central nervous system, was beneficently reflected upon all the functions dependent upon the latter. He was the first to insist that friction of the skin is required to dilate the paretic cutaneous vessels, and that the entire aim of treatment should be prophylactic. For these and other reasons, upon which the enormous beneficence of the Brand method and its superiority over all other bath substitutes are based; for the persistency, earnestness, courage, love of his kind; for the polemic and logical brilliancy with which he battled for this method for thirty years, Ernst Brand is entitled to be regarded as a benefactor of mankind and as a worthy representative of a profession whose devotion to suffering humanity is its chief ornament. The latter is brilliantly illustrated by his kindness and humane attention to the enemies of his country who had fallen into his hands by the fortune of war, and by the historical fact that Dr. Glénard, an eminent member of the Lyons medical faculty, who was among these prisoners, became so earnest a convert to Brand's method that when he returned to France he became its pioneer and missionary in that country. Despite opposition, which for political reasons was extremely bitter, the Brand method is to-day more frequently applied in France than in Germany. A valuable monograph by Tripier and Bouveret, professors of medicine in the Lyons School and physicians to the Red Cross Hospital there, attests the confidence of French physicians in this method. This book offers a complete clinical vindication of Brand's views, and has been translated by Pollak into German. "A prophet is not without honor save in his own country."

While the Brand method of treating typhoid fever is far from ideal, it offers to-day the most successful mode of management, as attested by its advocacy by our best clinical teachers. Peace to the ashes of the man who has added a powerful weapon against a disease in the combat with which the physician has hitherto stood almost as a passive spectator, never knowing where or when the foe would strike his most effective blow. By the strict Brand method, applied early and systematically, the physician becomes master of this usually fatal disease.

Medical Examiners on Pension Boards.—Many physicians who have been diligently working for and confidently expecting appointments to positions as medical examiners on pension boards under the McKinley administration may be interested in knowing that the sweeping order of Grover Cleveland, placing many of the department appointments under civil-service rules (which went into effect January 10, 1897), applies to medical pension boards. Unless the law is suspended, those at present occupying positions on the pension boards will retain office unless removed for incompetency or through resignation, in which case their places will be filled by competitive examination.—*Fort Wayne Medical Journal-Magazine.*

Clinical Department.

A CASE OF DISTOMUM HÆMATOBIUM (BILHARZIA HÆMATOBIA).

By HENRY T. BROOKS, M.D.,

INSTRUCTOR IN HISTOLOGY AND PATHOLOGY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; PATHOLOGIST TO BETH ISRAEL HOSPITAL; CONSULTING PATHOLOGIST TO H. S. G. S. ORPHAN ASYLUM.

The case presently to be considered occurred in the practice of Dr. George M. Edebohls, of this city, and is reported because of its rarity in this country and for its pathological interest.

The absence of any satisfactory description of this organism in American and English text-books on medicine, urinary diseases, and clinical microscopy may justify a short résumé of the biology and morphology of this parasite before entering upon the discussion of the case mentioned.

The parasite was discovered by Bilharz, in 1851, in Cairo, Egypt. It is found along the entire coast of East Africa, in Arabia, Mauritius, India, Abyssinia, South Africa, and Brazil. The sexes are separate. The female is 16.20 mm. long and is carried in a deep channel or furrow (*canalis gynæcophorus*) located upon the ventral surface of the male. The male parasite measures 12.14 mm. in length. The forepart of the body of the male is flattened, the posterior part cylindrical; the former bears two suckers situated not far apart. The intestine is simply forked, and reaches nearly to the hinder end of the body. The male genital organs, consisting of testicles and vas deferens, open behind the ventral suctorial disc. The female worm is cylindrical, thin. On the anterior part of the body are two suctorial discs. The female genital apparatus opens behind the ventral suctorial disc. The alimentary canal shows a bifurcation in front of the ventral suctorial disc. The two divisions, however, unite behind this disc into a single, somewhat undulating longitudinal stem. The ova, according to Lenharz, are 0.05 mm. broad, 0.12 mm. long, and carry at one end a long sharp spicule (ova with a lateral spicule are often seen); otherwise the surface is smooth. The ovum shell is moderately thick and without lid. Within the free ovum the embryo is visible and often manifests active movements. The ova are said to perish rapidly in impure water which contains decomposing vegetable or animal matters. In pure or salt water, however, the embryos soon break through the investing membrane longitudinally and swim freely about. They are somewhat wedge-shaped and covered with numerous cilia.

The fully developed worm inhabits the trunk and branches of the portal vein, the veins of the liver, mesentery, and spleen, and also the venous plexuses of the bladder and rectum. It is nourished from the blood. The ova, besides being found in the localities mentioned, also occur in the bladder wall, free in the bladder, and in the urine, which generally presents the signs of cystitis with hæmaturia. As the venous vessels are often densely filled with the parasites, congestion and stasis with escape of blood and ova occur. Catarrhal inflammations with great redness and swelling of the mucous membrane and submucosa develop in the rectum, bladder, and ureter. Numerous ova are found in the exudation which covers the mucous membranes, as well as in the underlying tissues. Later there may be ulceration, partial cicatrization, and in the bladder small cauliflower-like vegetations of the mucosa. During life, in addition to severe general disturbance of nutrition, the occurrence of blood, ova, and exceedingly minute fat droplets may be observed in the urine. Transmission very probably occurs through the agency of drinking-water, in which, as has already been said, the embryos escape from the ova within a few minutes. Whether the embryos first require an intermediate host, or not, is still unsettled (Lenharz). According to Sonsino,[1] however, the embryo penetrates into aquatic larvæ of some insects and into several species of arthropoda, and there becomes encysted. It does not undergo further development till it is liberated from its intermediate host within the human stomach. It bores its way thence, or from the intestine, into the portal vein. The animals which act as hosts are from seven to eight millimetres in length and three millimetres broad, and can, therefore, be removed from drinking-water by filtration.

J. A. R——, rabbi, aged thirty-two, married. Spent one year in South Africa, half a year in Port Elizabeth, Cape Colony, and half a year in Kimberly, returning thence to the United States in December, 1894. The journey occupied about six weeks. Three days after arrival in this country he noticed hæmaturia, which has been continuous to date (March 25, 1897), over two years. The great bulk of the urine was passed clear, but toward the end of micturition it became bloody and contained a number of larger or smaller coagula, varying in color from yellow white to blood red. He came under the observation of Dr. Edebohls on March 20, 1897. Examination at that time showed the general health fairly good. Neither kidney was palpable; there was no tenderness along the line of either ureter. By rectal exploration a little softness of the posterior wall of the bladder was made out, but there was no evidence of a tumor of any kind. A flat abscess, three inches in diameter and one inch thick, was observed in the right mamma. This abscess has been noticed within the last three weeks. A specimen of urine, passed in the presence of Dr. Edebohls, was voided clear, with the exception of a small number of blood-stained coagula and shreds, until the last few drops, which contained much blood. Microscopical examination[2] of this urine, made within half an hour of the time of voiding, showed innumerable isolated and partially decolorized red corpuscles, a large number of pus cells, occasional hyaline and finely granular casts of small diameter, and a number of small coagula and masses, composed chiefly of pus and blood embedded in fibrillated fibrin and mucus. In addition, there were observed within these coagula, and free in the field of the microscope, a number (two to fifteen to a field) of large ovoid bodies with one end gradually drawn out into a sharp spine, the other bluntly rounded. Examined under high power,[3] these bodies were seen to be composed of a moderately thick, homogeneous, transparent, highly refractive outer covering, enclosing an organized cellular structure, having a peculiarly arranged glandular apparatus made up of a tortuous duct ending by branches in an irregularly lobulated, opaque, and granular organ. This glandular apparatus was situated in the rounded end of the ovoid body. These bodies were at once recognized as the ova of some animal parasite, and by exclusion they were diagnosticated as those of distomum hæmatobium. To confirm this diagnosis, a fragment of a coagulum containing ova was placed upon a slide, gently crushed, and treated with plain water under a cover-glass. Almost immediately movements of a jerking, contractile character were observed at irregular intervals within the ova. After several minutes these movements became more and more active and violent, until suddenly the envelopes were rent asunder, the embryos escaped, and at once began to swim freely about. The embryo, when freed of its shell, was somewhat ovoid, lobulated, and provided

[1] Lancet, 1893, p. 621.

[2] Bausch & Lomb—Objective, two-thirds inch; ocular, one inch.

[3] Bausch & Lomb—Objective, one-sixth inch; ocular, one inch.

with a button-like knob located upon the cephalic end. The whole external surface was covered with innumerable actively motile cilia. The swimming movements of the embryo continued under the cover-glass at room temperature for from ten to twenty minutes, after which interval they gradually ceased. The cilia, however, continued their movements for a much longer period, and then, like the embryo which they formerly propelled, slowly came to rest. After the urine had stood for thirty-six hours, the ova contained therein no longer gave any evidence of life when treated with water.

CREOLIN AFTER ABDOMINAL OPERATIONS.

By J. MALSEED BELL, M.D.,

ST. JOSEPH, MO.

That fads travel in cycles is as well illustrated in the world of medicine as in that of society. The inhalation of medicated vapors, a therapeutic agent of no mean magnitude, has until recently been relegated to the realm of quackery or classed with the unscientific subdivision of "old granny" remedies. Inhalations were important agents with Hippocrates and Galen; Shakespeare refers to their curative properties in syphilis and a host of other ailments. Our American pioneers in medicine placed great store in the utility of vaporization, and in the first United States Pharmacopœia of Wood and Busch they were accorded a prominent place. During the past decade a vast tidal wave of new remedies swept the field, carrying with it many old and tried agents, leaving, instead, scientific compounds, precise and positive in action, elegant in appearance, and æsthetic in their exhibition. True, many of these have maintained a sphere of usefulness, and in the possession of some we feel we have progressed, but in none of them do we find an agent that at all times will take the place of an inhalation.

There is one class of cases, presenting irritability of throat, nose, or bronchi, accompanied with anorexia, which forbids the exhibition of internal dosing, in which there is no treatment possible other than inhalations; in others, while internal remedies are fairly well borne, comfort is maintained and convalescence facilitated by an adjunct in the shape of an inhalation; in all cases of nervous susceptibility with laryngeal and bronchial affections, any treatment is aided materially and many a night call prevented by the use of an inhalation.

In all such cases I find a charming remedy in ordinary commercial creolin, ten or fifteen drops vaporized twice or even once during the night, on a stove lid or on a tin plate over an alcohol lamp. But the field in which I value it most highly is in irritable conditions of the throat and lungs, existent with or occurring during the early convalescence of cases of abdominal section, hernia, and operations upon the scrotum—cases in which coughing, even slight, jeopardizes the safety of ligatures and stitches, and impairs, more or less, primary union. The following case illustrates the virtue of this agent in such conditions:

Mr. R——, aged twenty-two years, was brought to me, from Selden, Kan., in December, suffering with ulcerative appendicitis. The patient, when he arrived, had a distressing cough, but, the severity of the abdominal symptoms demanding immediate attention, no time was taken to ameliorate it. With the assistance of the family physician, Dr. W. H. Brown, an incision was made and an ulcerating appendix, three inches long, was removed. The cavity was drained and the patient put to bed, suffering with some shock. A hypodermic of strychnine nitrate, one-fortieth grain, developed some tetanic spasms, which with the incessant cough threatened the integrity of the wound, if not the life of the patient. By the second day the temperature had returned to normal, but the cough persisted, and with it an irritable stomach, that was a constant menace to convalescence. Creolin was vaporized in quantities of ten drops twice during the first day and twice during the night, once the second day and succeeding night, and until convalescence was so far established that other means could be employed. The patient sat up on the sixteenth day, and on the twenty-first went home.

The relief afforded by breathing an atmosphere at once moist and soothing is never more fully appreciated by the patient as well as the physician than in such a case as the one quoted. Not only does the creolin possess the virtue of relieving the patient, but its vapor in the room during the dressings tends to destroy the more or less pathogenic bacteria that must emanate from respiratory organs undergoing a pathological process.

THE RESULT OF A WESTERN "HOLD UP."

By EUGENE F. TALBOTT, M.D.,

FLANDREAU, SO. DAK.

On January 20, 1896, I was called out fourteen miles to see a case of gunshot wound. The patient, a young man aged twenty-two, had received five bullet wounds at 8 P.M., January 19th. On account of the distance from town I was unable to get there before the stated time.

After making an examination, I discovered that he had been shot five times with a 38-calibre revolver, as it afterward proved to be. The wounds were as follows: No. 1, perforating wound, two inches above and one-half inch to the right of McBurney's point. The bullet was located about four inches to the right of the vertebral column, and one and one-half inches above the crest of the ilium. It was quite deeply buried. No. 2, perforating wound, four inches to the right of the right edge of the sternum in the second interspace. The bullet which presumably caused this wound was located in the posterior part of the axillary space. No. 3, wound near the angle of the left inferior maxillary bone. The bullet followed a downward and inward course, and was located beneath the skin at a little to the left of the second dorsal vertebræ. No. 4, bullet took off a portion of the end of the nose. No. 5, bullet made a groove in the right cheek. Wounds Nos. 1 and 3 were made while the revolver was in close proximity, for the skin was considerably burned. The patient was suffering a minimum degree of shock, but more severely pain in the abdomen. There was no tympanites.

I gave him a hypodermatic injection of one-fourth grain of morphine sulphate to quiet the pain and peristalsis. I dressed the wounds with occlusive iodoform dressing. No probing was done.

The next day I found him resting easily. He had had an apparently natural movement of the bowels. The chest wound was emphysematous. He had expectorated small quantities of blood. Temperature,

99° F.; pulse, 90; respiration, 19; urine normal. There was evidently no perforation of the bowel, so I put him on small doses of magnesium sulphate. He made an uneventful recovery. Since then I have removed the three bullets which remained in his body, and he is apparently as healthy as before the injuries.

The case is given to show the apparent absence of pyogenic cocci in a comparatively new country, as you will see from the above that there was no suppuration in any of the five wounds. It is very likely, as the country becomes older, bacteria will be introduced by the surgeons (?) or others. Then we Western practitioners will of necessity have to practise true aseptic surgery in every sense of the word.

VULVO-VAGINAL ANUS.

By JAMES J. KEYES, M.D.,

BROOKLYN, N. Y.

I DESIRE to report the following case as one of interest: On February 14, 1897, I was asked to see Mrs. O'N——. I found her in the dilatation stage of labor, head presenting, membranes intact, cervix dilatable, with a generally contracted pelvis. The fœtal heart sounds could not be distinguished, and the woman claimed to have felt no fœtal movements for several days.

Mrs. O'N—— was born in Ireland, aged twenty-six years, married three years, and pregnant for the first time. She last menstruated on April 5, 1896. When making the vaginal examination the lower bowel felt as though it contained hardened fæces, and I gave instructions to have it cleared.

On my return to see the patient a second time the nurse told me she could not give the enema, being unable to find the anal orifice. Closely examining the patient, I noted the absence of the anus, although to the eye its presence was distinctly suggested by a depression and a circular puckering of the skin, darkened in color, situated about one and three-eighths inches from the posterior commissure. I discovered that the rectum opened into the vagina just within the remains of the hymen—a transverse slit admitting a large finger, possessing but little of the elements of a sphincter, the lips of the aperture being thicker than the rest of the recto-vaginal septum. The mass I had mistaken for fæces was the so-called perineal body, enlarged and rather firm in consistency, the apex extending to the middle of the coccygeal bone. The rectum was smaller than usual, tubular in shape, and with no marked dilatation.

Instead of dipping down at right angles to the vagina and forming the anal canal, it came in front of the perineal structures into the vagina. The remains of the hymen were plainly visible, more so at the sides and in front than behind, the termination of the rectum being just inside the point at which the hymen begins to protrude from the posterior wall of the vagina. The vulvo-vaginal outlets in every other respect seemed to be normal, and were undoubtedly the organs of a woman who had as yet not borne a child.

The patient, who was not very intelligent, was totally unaware of her condition, as were also the members of her family. Her mother, who had twelve children, is dead, and from all accounts was ignorant of her daughter's deformity. There was no history of incontinence of fæces, Mrs. O'N—— saying she had no trouble with her bowels, except to have a movement four or five times a day.

I called two physicians to see the case with me. We concluded that the child was probably dead, and decided to deliver with axis-traction forceps. Chloroform having been administered, the membranes were ruptured, liberating a dark, thick, grumous liquor amnii.

The vertex presented at the brim, the position being O. D. P., rotation occurring during descent of the head. The presence of a well-marked "retraction ring," the contraction of the birth canal, and the anomalous condition and unusual rigidity of the pelvic floor rendered the case a most difficult one, the delivery of the shoulders giving the greatest trouble. The birth of a decomposing child, weighing eleven pounds, was finally accomplished. The perineum was torn to the depth of about one inch, and for a short distance the partition between the vagina and rectum, the immediate repair of the parts not being attempted, partly on account of the exhausting character of the labor, both to the patient and attendants, and with a view to perhaps a more radical operation later on; otherwise the woman made a good recovery.

I do not usually make use of the rectum as an obstetrical aid; in this case, however, it would have materially helped, and I should have gladly used it had it been possible.

When I say that the confinement took place in the basement of a tenement house, it will be understood that the difficulties in the strict observance of the rules of antiseptic midwifery were almost insurmountable. Still a heroic attempt was made to conduct the case as cleanly as possible; and, while it would scarcely be satisfactory to a Garrigues, the subsequent non-septic course of the puerperium leads us to believe that our efforts were not unavailing.

The chief interest in the case lies in the ignorance of the woman as to the existence of the malformation.

THE EPIGLOTTIS AS A PINCUSHION.

By J. M. W. KITCHEN, M.D.,

EAST ORANGE, N. J.

À propos of Dr. Fulton's article on foreign bodies in the air passages in the issue of the MEDICAL RECORD of February 20th, and in further relation to the tolerance of the air passages to foreign bodies, the following experience may prove interesting:

A colored girl of about twenty years of age presented herself at my clinic at the Memorial Hospital Dispensary, saying that there was a pin in her throat. As she was not the least alarmed and had not the first symptom of such a condition, her statement was disbelieved. Examination of the pharynx gave no sign, but the laryngoscopic mirror at once disclosed that the point of a pin was embedded in the cushion of the epiglottis, and its head was pointing down "the wrong way." The instruments at hand were not adapted for the emergency. My fellow specialists will imagine the situation. If that pin dropped, where would it go? I took the girl to my residence as carefully as possible, quietly prepared for tracheotomy, and used all the forceps I had, but none was of the right shape to grapple with the pin in its peculiar situation. Finally, I made a piano-wire loop through a bent cannula, and, running it over the head of the pin, dragged it around to position transverse to the laryngeal opening. Then, by introducing the index finger, I was just able to pass the nail over the middle of the pin, and, bearing downward and forward strongly, the pin was dragged to the outer world, much bent and leaving pretty bad scratches in the girl's throat. But during all this proceeding there was not the slightest sign of irritation in the patient, either direct or reflex. No cocaine was used or needed. Evidently some human beings have less nervous irritability than others.

Society Reports.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, March 5, 1897.

GEORGE F. SHRADY, M.D., PRESIDENT PRO TEM.

Result after Operation for Carcinoma of Breast.—DR. CHARLES MCBURNEY presented a woman, about forty-five years of age, in illustration of the result of removal of the breast for carcinoma. The operation, performed about four weeks ago, was that known as Halsted's, whereby the entire pectoralis major was removed, with the exception of the clavicular fibres, and the whole of the pectoralis minor. In the present case the tumor was rather a large one, and the large wound area was diminished by purse-string suture. The first criticism which the bystander was likely to make was that the operation was a very mutilating one, and the question would be asked whether there was not too much crippling to justify the end. The case presented proved what little basis there was for either of these criticisms. The scar was a comparatively small one, and the patient was able to make all of the normal movements of the arm with sufficient power. The result of these operations had upset some anatomical notions with regard to the great importance of the lower half of the pectoralis major.

DR. SHRADY said he had performed this operation several times, and had been surprised to find how much motion was left in the arm. In one case, in which he removed the whole pectoralis major, the patient was still able to put the hand on the opposite shoulder, thus showing how much the anterior fibres of the deltoid had to do with that motion.

DR. MCBURNEY added that he had been much pleased at the facility with which one could accomplish the main object, that of dissecting out the axilla to the highest point. It could be done only by removal of the pectoral muscles.

THE PRESIDENT remarked that their removal laid bare all of the vessels, and shortened the operation very much.

Correction of Deformity Caused by Colles' Fracture.—DR. MCBURNEY presented a boy of about sixteen years, to show the result of an operation for the relief of deformity and impaired function caused by a Colles' fracture of the radius, one and one-half inches from the lower extremity. Perfect union had resulted after the fracture, with well-marked silver-fork deformity, loss of power of flexion at the wrist, partial loss of flexion of the fingers, a good deal of pain on motion. While recognizing the importance of doing something to give relief, he did not think he could with propriety attempt refracture without a cutting operation. Cutting down upon the bone, he divided this as nearly as he could in the line of the fracture, which ran somewhat obliquely. He was then able to put the parts up in proper position and retain them with a plaster-of-Paris splint. The splint had been removed a week since. There was very little deformity left, and the restoration of function had been extremely satisfactory. Replying to an interrogatory by Dr. Dana, he said the nerve had not been injured, but simply stretched by the displaced bones. Dr. McBurney added that it was common to see cases of this deformity, the doctor being apt to tell the patients that disability would gradually disappear. But it did not, and they went on indefinitely with great loss of function. The deformity was nearly as common as that left by Pott's fracture, and that was very common.

Case of Insanity Cured by Thyroid Extract.—DR. C. L. DANA made the following report: "The patient is a young lady, unmarried, twenty-eight years of age, with no especial neuropathic taint in the ancestry. One older brother had Basedow's disease from the age of thirty-five to thirty-nine, when he was cured, and has remained so; one younger sister had hystero-epilepsy; a second brother is of a nervous temperament, and suffers from insomnia; and another sister has migrainous attacks.

"The patient herself was a healthy girl until she reached the age of twenty-four. She was of a quiet and serious temperament, possessing good self-control and a good bodily physique. At the age of twenty-four she received a severe shock, and following it had a state of mental confusion, with some depressing delusions. For about five months she suffered from a mild form of confusional insanity, but recovered completely and went to work. Four months later she had a relapse, lasting about two months. In the spring of 1895 she again began to suffer from the same kind of mental disturbance that she had had two years before, she being then twenty-six years old. These symptoms increased, and she suffered much from insomnia; she had delusional ideas about an influence working upon her, and about things being wrong about her. She had at times hallucinations of hearing voices. She was unable to apply her mind to anything; talked incessantly, but in a confused, incoherent way. She at times was depressed and cried, but never became violent.

"As her malady increased, she showed signs of erotism in various ways, dwelling much upon the subject of marriage and upon her experiences with the young men with whom she had been acquainted. She did not lose her appetite or suffer in physical strength. She was taken to a 'rest cure,' and then to a quiet place in the country, where her symptoms remained about the same on the whole, becoming slightly worse, however, and at the end of about nine months she was placed permanently in Dr. Watson's sanatorium at Fishkill, where she has been now for nearly a year, so that her present mental trouble has lasted almost two years. During all this time there has not been any great variation in the symptoms, except that they were slowly getting worse, and the general clinical features of the malady are those of mental confusion, with a tendency to depression at times, and a general tendency to dementia.

"It was thought at one time that some disorder of the pelvic organs might be at the basis of her trouble, and she was examined by Dr. E. Cushier, who reported that everything was perfectly normal. Blood examination showed some anæmia, but nothing very marked. There was no disturbance of the functions of the kidneys. On account of the steadily progressive character of the trouble and the apparent evidence of serious degenerative changes coming on in the brain, the question finally arose as to whether an operation for the removal of the ovaries should not be attempted. The patient was seen several times by Dr. Allan McL. Hamilton and Dr. B. Sachs, of this city, and was for a long time under the care of one of the latter, while at the sanatorium. I advised, before attempting any such operation—which was only suggested as the very last resort—that the patient be placed upon the thyroid extract. Physically she presented none of the symptoms of myxœdema, except that she had been growing stout and that her face had a white, pasty look. But she had no falling of the hair, dryness of the skin, or myxœdematous deposits in the body at all. The thyroid gland could be felt, and did not seem to be specially small. I should state that she had, at the end of the first year of her trouble, been treated with thyroid extract, but without any results. This time it was determined to push the drug to the point of tolerance, and see if any improve-

ment could be obtained. This was done, treatment having been begun about five weeks ago, and being carried on by Dr. Watson, of Fishkill, in whose care the patient was. The five-grain thyroid tablets were given, beginning with fifteen grains a day, and gradually increasing the dose until she was taking sixty grains a day. At the end of two weeks symptoms of improvement appeared, and at the end of four weeks she seemed almost entirely rational. There was then a slight relapse, but at the present time, three months from the beginning of treatment, she has become thoroughly sane. She talks intelligently and coherently, has no delusions, and writes a sensible and well-worded letter. The improvement has been so striking and progressive, and so definitely associated with the use of the thyroid, that there can be no doubt as to its being the cause of the change. Along with this improvement there has not been much alteration in her physical condition. She has lost ten pounds in flesh, her pulse rate has gone up at times to 90 or a little over, and she is physically somewhat weak, showing this especially in going upstairs; but there has been no increased flow of urine, and no change in the urinary secretion in any way. Her appetite has continued good.

"The interest of this case is twofold: In the first place, it is a very striking illustration of the therapeutic effect of thyroid extract in a case of insanity in which none of the ordinary symptoms of myxœdema were present. The insanity had been pronounced to be a degenerative one, and a bad prognosis given. In the next place, the fact that a brother suffered from Basedow's disease in a very typical way is a curious illustration of what I might call a thyropathic 'tendency' in the family."

The accompanying table, prepared by Dr. Watson, shows the progress of the case during the first two months:

In What Cases of Insanity is Thyroid Extract Useful?—Dr. F. P. Kinnicutt believed, with the author, that the treatment of insanity with thyroid extract had not been very encouraging in this country. Therefore the case reported was the more interesting. Dr. Kinnicutt had seen the treatment tried, and had himself employed it in cases somewhat resembling Dr. Dana's so far as the mental symptoms were concerned, but without improvement. He thought the very fact that in a large majority of the cases the treatment was without effect, while now and then it was so strikingly successful, would indicate that in the latter the trouble was probably connected with diminished or perverted secretion or function of the thyroid gland. It was known that there might be interference with the function of the gland and that structural change might even exist without any anatomical signs being detected during life. That fact was sometimes illustrated in exophthalmic goitre. All knew how extraordinary was the improvement in the mental symptoms, as well as in all the other symptoms, in myxœdema. He repeated that it seemed fair to assume that in the cases of insanity in which the extract was of benefit, there was destruction or perversion of function in the thyroid gland.

Dr. Weir, referring to the influence of thyroid extract in disease of the thyroid gland, said all would remember how Kocher had startled the world by the announcement that he treated goitrous tumors by this extract, when formerly it had been his custom to operate. In this country there had been little experience in this line. Dr. Weir had used the extract in three cases with marked benefit, in all the tumor having been of considerable size, in two chiefly parenchymatous, in one more like an adenoma. On the other hand, four cases in which it had been pushed to the degree of producing constitutional effects showed no improvement whatever.

Dr. Dana replied to Dr. Kinnicutt's interrogatory that he thought the cases of insanity in which thyroid extract proved beneficial probably were cases in which there was some derangement of the thyroid gland. In one instance he had to give up the drug, on account of its erotic effect—the young woman wanting to marry the nurse or anybody else. He had seen the pulse run up under its influence to 160, but in no case had it caused any serious results.

Loose Cartilage in Knee-Joint Shown by X-Ray Photograph.—Dr. Weir presented x-ray photographs, showing, to his surprise, two loose cartilaginous tumors in the knee, one being free in the joint, the other connected with the bursa of the biceps tendon. The latter had hampered motion most, and was removed. The piece in the joint showed most plainly under the x-ray, and probably contained some bone.

Asepsis of the Hands.—Dr. R. F. Weir read the paper (see p. 469).

Dr. William T. Bull did not doubt that all had

felt that some improvement on the bichloride method was desirable. The varying reports from culture tests had been rather bewildering. He felt himself under obligations to Dr. Weir for testing these methods, and he was disposed to try the one recommended, and for which there had certainly been a very favorable showing. Perhaps one criticism could be made. At least, it would have been more convincing had clinical cases been reported, showing the result of wound behavior under the different methods. It was known that there were some germs which existed in the epidermis and on the hands, which apparently did not interfere with primary union, so that while it was very desirable to have a method of disinfection which answered all the laboratory tests, yet it was a satisfaction to know that a method need not be absolutely perfect when tested by cultures in order to give excellent clinical results. He inquired of Dr. Weir whether he had obtained primary union in a larger percentage of cases by the method which showed absence of cultures from the hands in ninety-seven per cent. than by the old bichloride methods.

Dr. McBurney said he would not repeat the views expressed by Dr. Bull, as he was about to do. Doubtless, however, the laboratory tests were in themselves of great value. Speaking alone of his own experience, some time ago he had taken up the permanganate-of-potassium and oxalic-acid method, but after some time became, as others had, very tired of the permanganate. It was disturbing to the finger nails and difficult to remove even with the use of oxalic acid. The hands were kept continually in a state of roughness and discomfort, and for that reason were probably more difficult to sterilize next time. While giving up the permanganate, he liked the influence of oxalic acid very much. It seemed to do what no other agent had done, namely, take away rapidly and very perfectly every particle of loose epithelium and left a smooth condition of the hands, which was one essential to asepsis. To some hands, however, it was irritating. On giving up permanganate, Dr. McBurney began to use ammonia to a large extent, and had found it of great value. The laboratory tests had not been sufficiently numerous to enable him to speak of its absolute germicidal powers, but the clinical results had been extremely satisfactory compared with other experience. Adding a drachm of ammonia to an ordinary bowl of hot water rendered it softer and infinitely more cleansing in combination with soap than was water without ammonia. In all writings on sterilization of the hands, he had failed to find much reference made to cleansing them after operations, yet it seemed to him that clinically such practice was of great importance. It made a great difference whether the hands were cleansed immediately after an operation with respect to the result on the next operation, and yet it was often neglected. If the hands were washed immediately after an operation, particularly if ammonia were used, every particle of blood would be gotten rid of with the greatest facility, for ammonia broke up the blood almost on contact. If the hands were not sterilized at once, the process would be much more difficult at the next operation, and meanwhile a good culture medium would be present for any germs that might get upon the hands. The effect of ammonia water upon blood under the nails or on any part of the hands was remarkable, and would astonish anybody who had not made use of it. The blood would disappear almost instantly, and the nails, which had been quite reddened and soiled, whitened within a quarter of a minute while being brushed in ammonia water. Being asked what was the germicidal power of oxalic acid, Dr. McBurney said he thought its chief value was mechanical.

Dr. Beverley Robinson recalled the fact that in his early student days Nélaton, of Paris, washed all of his amputation wounds with alcohol. We had been told this evening that alcohol was useful in rendering the hands aseptic. If useful on the hands, why not in wounds? A few weeks ago he had witnessed Dr. Biggs inject some antitoxin, and before making the injection the latter drew some alcohol into the syringe and let it burn. It had impressed him as a convenient way to render the syringe aseptic. If alcohol was not one of the best disinfectants, still one could see many ways in which it could be utilized by the general practitioner, who usually had some at hand. He would ask why surgeons had given up Labarraque's solution. It was formerly used a great deal.

Dr. George L. Peabody said the reminiscences brought forward by Dr. Robinson reminded him of observing Recklinghausen, many years ago, dip his fingers into acetic acid after making an autopsy, and was told that he invariably did so when he feared infection. Dr. Peabody followed that practice for years afterward when making autopsies at the New York Hospital, first washing the hands with soap and water and then with acetic acid. It had always prevented, it seemed, the development of anything like an infected wound. On one occasion he went directly from the autopsy room to the ward, and there found a woman bleeding profusely, almost exsanguinated, from retained placenta. Hasty action was demanded, and without any further washing of the hands he passed one up to the fundus of the uterus and removed the adherent placenta. The bleeding ceased, the temperature did not rise, the woman made a good recovery. Acetic acid had an agreeable effect upon the skin. It softened the epidermis and left the hands in a smooth condition. Twenty-five per cent. of acetic acid and the rest glycerin constituted an excellent application for chapped hands and face in the winter.

Dr. Wyatt Johnson, of Montreal (invited guest), said they had in the hospitals at Montreal made some laboratory tests as to the efficacy of the sterilizing methods used during operations, and some of the difficulties spoken of by Dr. Weir were noticed, the chief one being that the more effective methods of sterilization were hard on the hands. The surgeons in the Montreal General Hospital, and also those in the Victoria, still used permanganate of potassium and oxalic acid largely, also corrosive sublimate in water and in alcohol. Alcohol alone had not been tried very much. He was glad to hear of a method which offered prospects of good germicidal results without injurious effects on the hands. Regarding the germicidal properties of chlorine, he believed this agent constituted one of the ingredients of some secret preparations, which had been put up in a form not to irritate the hands.

Dr. L. A. Stimson, invited guest, thought he could give some of the clinical testimony which Dr. Bull had considered desirable for establishing the value of the method described by Dr. Weir. He had been using it about four years, both at the New York Hospital and at the House of Relief. During the last two years he had collected the statistics from his own service in the two hospitals. In the House of Relief there had been no case of wound suppuration during the two years. In the New York Hospital there had been but one case of wound infection, and in that instance, as appeared from his report published a year ago, the infection was probably independent of the hands. The clinical test, therefore, had been favorable to the use of this combination of chloride of calcium and carbonate of sodium. Dr. Stimson had been rather surprised to hear Dr. Weir speak of the cooling of the cream as an indication of the time to throw it aside and take the other agent, for he had himself noticed a cooling effect on its first application, which, however, soon gave way to a feeling of warmth in the hand.

He crushed the crystals into the size of a pea. A powdered preparation must be avoided.

Dr. Weir made some closing remarks. He said Dr. Stimson had answered the question put by Dr. Bull, that there were clinical results to support the laboratory tests. His own opinion was that the demand for laboratory tests had been carried to an extreme degree. In answer to Dr. Robinson's inquiry he would say that alcohol was not used in fresh wounds, for the reason that it was not desirable to meddle with such wounds. They would heal without it. If they were infected, alcohol was one thing which could be used, but it was not so good as some other things. Regarding acetic acid, mentioned by Dr. Peabody, it had been used, and in Germany vinegar was employed. It was also a deodorizer. As a disinfectant it had not great power.

Regarding the cooling effect of the soda, he had referred to the second, not the first cooling effect. It was merely a house surgeon's dodge, and was observed so frequently that he had thought it worth while to call attention to it, as an indication that the rubbing with this agent had been continued long enough.

Appendix with Large Concretion.—Dr. Charles McBurney presented the specimen with the following history of the case. A man, twenty-three years old, was well until three months before he saw him, when he had for the first time very severe abdominal pain ushered in by chill. The pain soon located itself in the right iliac fossa, persisted, and the patient remained abed for two weeks. Up to the time Dr. McBurney saw him, which was three months later, he at no time was free from a sense of soreness on touch over the region of the appendix, but there was no fever and no other sign of ill health. Dr. McBurney inferred from the history and the presence of some pain that there must have been a considerable degree of inflammation at the appendix, that adhesions had probably been left, and perhaps septic material was in the appendix. Consequently he operated, but found rather a curious condition of the appendix. There was no peritoneal involvement whatever, but the appendix, which was coiled upon itself, was distended throughout, except at its attachment to the colon, with a concretion which easily broke up when the appendix was opened after removal. The vascular condition of the appendix was normal and macroscopically he could detect no change in the mucous or other coats.

Dr. McBurney believed that appendicitis always depended upon some interference with drainage from the appendix, whether the obstruction was brought about by a concretion or other cause. As soon as the exit of the secretions into the colon was interfered with the conditions became favorable for the development of bacteria. He supposed the concretion in the present case began to form at the distal end, and gradually increased until the entire lumen was filled to near the colon.

Gangrenous Ovary Caused by Twisted Pedicle; Simulation of Appendicitis.—Dr. McBurney presented a gangrenous ovarian tumor caused by twisting of the pedicle. The young girl had been ill for a week with no antecedent history. The onset of her symptoms was very sudden, and presented all the usual signs of a sharp attack of acute appendicitis—localized pain, distention, vomiting, constipation, etc. When he examined the patient the abdomen was rather distended, yet the signs were thoroughly satisfactory to him of a rapidly forming abscess having pretty well defined walls due to appendicitis. When, however, he opened the peritoneum he found no adhesions in that neighborhood at all, but came immediately upon a black-looking tumor where the appendix should be, and which was found to be the ovary with a complete twist of its pedicle.

Dr. Bull had met with a similar case. The symptoms were acute; the tumor was a little lower than the ordinary position of the appendix. The girl had not reached the age when ovarian tumors were common, and vaginal examination had not been made. The history pointed clearly to appendicitis, but on opening the abdomen he came upon a black-looking tumor of moderate size, which was the ovary with twisted pedicle. Some of the putrescent contents escaped, but the patient made a good recovery.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNÆCOLOGY.

Stated Meeting, March 25, 1897.

S. Marx, M.D., Chairman.

Nephrectomy for Tuberculous Kidney; Two Cases.—Dr. John O. Polak presented two kidneys showing almost complete tuberculous destruction. One was removed from a patient aged twenty-six years, with tuberculous family history, no pulmonary tuberculosis, pain for four years which a doctor called hepatic colic. When he was seen by Dr. Polak there were blood and pus in the urine. He performed lumbar nephrectomy, and the patient died six days later of acute uræmia.

The second specimen showed a similar condition, but the pelvis of the kidney was greatly dilated, and another physician had made the diagnosis of ovarian cyst. A provisional diagnosis of cyst of the kidney was made in the hospital. Anterior incision was made, the kidney was removed, and the patient made a good recovery. An interesting fact was that in both cases intravenous infusion of saline solution was resorted to, but in the second case it was done during the operation and the kidneys acted at once, whereas in the first or fatal case, the infusion was not made until the second day, when almost absolute suppression had already taken place. But this injection and one subsequently caused the remaining kidney to act, the first time excreting twenty-six ounces, the second time thirty-six ounces of urine. In spite of this, coma developed and the patient died.

Dr. Polak also presented the uterus which formed the subject of his paper read later.

Cyst of the Urethra in a Female Infant Two Weeks Old.—Dr. H. C. Coe reported the case of his youngest gynæcological patient, a female infant two weeks old, who, when he was called to her, had been straining at intervals for two days, and was supposed to be suffering from some bowel difficulty. Before that everything had been perfectly normal. The temperature went up to 103° F., and suddenly a small tumor appeared at the vulva. During the next twelve hours it protruded still more, attaining the size of a large grape. Its appearance was that of a blood clot. The patient was still having the attacks of tenesmus. The question arose whether there was inversion of bladder or uterus, whether there was blood clot or other condition not easy to determine. The tumor ruptured and thick bloody fluid escaped. The bladder, which was distended with urine, could be palpated. The vagina was normal. After considering for some time, he decided to excise the mass for diagnostic purposes, although he afterward regretted it, fearing he might have excised the bladder, for the mass had the appearance of the bladder with the two ureters entering it. But his fears proved unfounded, for the patient's symptoms disappeared; she passed water normally for the first time in a number of hours, the distended bladder contracted, and there was no further trouble. He thought the tumor must have been a congenital cyst of the urethra.

Case of Hysterectomy for Septic Puerperal Metritis; Recovery.—Dr. Polak read the history of the case of which he had just presented the specimen. The patient was a Pole, age thirty-three, confined by a midwife, admitted to the hospital twenty-three days later in a state of marked sepsis, rigors occurring several times a day. Her appearance was characteristic of sepsis. There was evidence of septic pneumonia in the apex of the left lung. Vomiting, abdomen tympanitic, pain exquisite in the left iliac fossa, uterus enlarged; the cervix large, soft, lacerated bilaterally, thick purulent discharge escaping. The temperature rose to 102° F. in the afternoon; pulse, 120 to 140. The pneumonia improved in the hospital. Treatment supporting and stimulating; vaginal and intra-uterine irrigations. The septic symptoms continuing, after some days, January 23, 1897, hysterectomy was performed by the vaginal route. During gentle preliminary curettage the anterior wall of the soft uterus was punctured. The appendages were removed with the uterus. Clamps were employed. The operation lasted thirty-two minutes. The uterus was very friable. The temperature remained high several days, then fell, and convalescence went on uninterruptedly. During the first twenty-four hours there was almost complete suppression of urine, and this continued to a degree for a week. Saline infusions were resorted to. An interesting fact was that sepsis had extended to the broad ligaments, while the tubes were not involved, showing that the extension was by the lymphatics. On pressure pus exuded freely from the walls of the removed uterus.

The chairman, Dr. Marx, thought Dr. Polak had been very fortunate in saving his patient. Let what would be done the patients usually died. He had himself not been able to save any by hysterectomy.

Dr. Coe said the difficulty which he had always found in selecting cases of puerperal sepsis for hysterectomy was in deciding whether the sepsis was confined to the uterus. He had seen several cases in consultation in which the question of hysterectomy arose, and in all it was concluded that the sepsis had extended too far, although in one instance the patient was placed on the operating-table, and at the last moment it was decided not to operate, as it was believed she would die if the abdomen were opened. Yet this patient recovered, as did two or three others whose condition had seemed hopeless. He had removed the puerperal uterus several times for other reasons, and could confirm the statement that its removal was easy in spite of its vascularity.

One patient had a very severe form of infection which had continued two weeks, during which time he had curetted several times. Life was despaired of. The uterus was movable, no exudate around it. It was simply a case of severe sepsis, the foci being limited, as proven by subsequent events, to the uterus. He curetted again and was about to discontinue, when the curette slipped into an abscess cavity within the uterine walls about two inches, most offensive pus escaped, and from that time the patient went on to recovery.

Dr. E. B. Cragin said there were two facts favorable to success in the case reported: (1) It belonged among the cases of rather long duration of the septic process. (2) There was thickening of the field outside the uterus. This was the class of cases of puerperal sepsis most likely to terminate in recovery after vaginal hysterectomy. Dr. Cragin had performed hysterectomy in four such cases, two with recovery, two with death. But the difficulties of determining the points stated by Dr. Coe, whether the source of infection was limited to the uterus, and whether the general infection had gone too far to save the patient, were so great that mistakes must be made, and some cases would be allowed to pass without operation which might have been saved, and others would be submitted to operation which ought not. In puerperal sepsis the hysterectomy ought to be vaginal, and clamps ought to be employed. The case reported in the paper was also interesting in that it furnished further proof that suppurative cellulitis did sometimes occur in the pelvis.

Dr. Vineberg took the same ground as the last speaker, that there was a great difference between septic cases running an acute course and those running a chronic course. He had had one case at least in which vaginal hysterectomy could not have been done as well as abdominal, owing to involvement of other organs in addition to the uterus. The sepsis had been going on two months. This patient recovered. Another case was mentioned in which abdominal hysterectomy failed to save the patient. In one instance he had had an experience like Dr. Polak's perforating the soft walls of the uterus during curettage.

Dr. A. P. Dudley would confess that he had never done vaginal hysterectomy for puerperal metritis, but had saved ten cases by minor pelvic operations. He did not undertake hysterectomy for the reason that he regarded it as an extremely dangerous procedure in these cases, adding the shock of anæsthesia and of a grave operation to an existing formidable disease. One should resort to milder measures if possible. He would do hysterectomy only in case there was commencing general peritonitis, indicated by tympanites, etc. Prior to that he would evacuate any local collections of pus which could be found, and apply cold pack, and give antifebrin or other coal-tar preparations for elevation of the temperature.

Dr. Gallant believed in taking the uterus out before septic pneumonia or any form of distant sepsis developed. He regretted not having done hysterectomy in one case before the development of double pneumonia, which caused the patient's death.

Dr. Polak said it was because of the localization that he operated in his case. Pus poured from the uterus. There was some thickening of one broad ligament and pus in the other. It was for metritis, not endometritis or peritonitis, that one removed the uterus. If there was only a local abscess it was sufficient to empty it without doing hysterectomy. He would certainly have to differ from Dr. Dudley if he treated peritonitis with coal-tar products.

Further Remarks on Septic Peritonitis, with Special Reference to the Antistreptococcus Serum.—Dr. Egbert H. Grandin read the paper (see page 473).

Dr. Johnson, of Boston, being invited to open the discussion, related a case which he had sent to the hospital, where the abdomen was opened for pus tube and abscess of the ovary. The abscess ruptured and the peritoneum was soiled. On account of adhesions the operation lasted about three hours. After forty-eight hours there were symptoms of sepsis; pleuro-pneumonia developed on the right side. Antistreptococcus serum was employed, and the symptoms of sepsis had disappeared, although the patient had yet fully to recover from her pleuro-pneumonia.

Dr. Paul Gibier, having been invited to be present, spoke of the production of antistreptococcus serum. It had been supposed that large doses of it were dangerous, or that the agent employed to make it antiseptic might cause poisoning if large doses were used. Dr. Gibier, however, had devised a method whereby the serum could be prepared and kept without the use of an antiseptic, and in such a manner that the serum was innocuous, but retained its antistreptococcus powers. It was for that reason that Dr. Grandin could inject nearly two ounces with impunity. It was difficult in the horse to produce the antistreptococcus serum of

such a strength that a comparatively large amount was not required at a dose. Hence the advantage of so preparing it that it could be used without danger from the quantity employed.

Dr. Coe said he had seen Dr. Grandin's second patient when he operated, and thought the recovery could have been due to early cleansing out of pus cavities. Having in hospitals seen many cases of diffuse septic peritonitis, and never having seen one subject recover, he remembered that the question arose whether Dr. Grandin's case was one of true diffuse septic peritonitis. We must make a distinction between multiple abscesses, no matter how extensive, and diffuse inflammation of the peritoneum. It was sometimes difficult to differentiate between the two, even with the abdomen open.

Dr. Vineberg had seen antistreptococcus serum used in two cases. One case was his own; the patient had septic peritonitis, but died within two days in spite of the serum. The other patient, not his own, also died, the case being one of septic peritonitis from appendicitis in a child of five years. But the serum was now before the profession, and the public asked with regard to its value. This would have to be determined by experience. Personally he doubted whether it would cure really bad cases. But it did not make the patients worse. He had not seen any depressing effects on the heart.

Dr. Richards read the history of the case of puerperal sepsis in which the patient had recovered under Mamorek serum, and which he had referred to at another meeting recently.

Dr. A. L. Fisk thought it was a very important question whether any given case was one of general septic peritonitis. He remembered a paper of Dr. McBurney's, read before the Academy of Medicine, in which he reported a number of cases of apparently general septic peritonitis from appendicitis, and Dr. Grandin's, he thought, was very similar to those. Dr. Fisk had himself seen some such cases, and upon examination they were found to be cases of large collection of pus in the pelvis walled off from the general peritoneal cavity. Or the pus might cross over and form a collection in the opposite iliac fossa, or reach certain other localities, and yet not invade the general peritoneum. It had been Dr. Abbe's practice not to flush in these cases, but to wipe out. In fact in all cases he had given up, and Dr. Weir and others had given up, the habit of flushing the abdomen, for the feeling was that in flushing the danger of spreading the infection more than offset the value of the cleansing, especially as the latter could be better accomplished by wiping.

Dr. P. A. Harris thought physicians should encourage rather than discourage those who were willing to try a method which offered some prospect of saving cases generally recognized as desperate and claimed by some to be uniformly fatal. Personally he had some fear of antistreptococcus serum, and had not had the courage to try it, but in view of the good accomplished by diphtheria antitoxin there was reason to hope that good would come from it.

Dr. R. A. Murray said he had not used antistreptococcus serum, but he saw no reason why it should not be employed as soon as it was concluded that any given case had passed beyond the reach of surgery and before it had become desperate from systemic infection. Or, after using proper surgical means, but unsuccessfully, resort might be had immediately to the serum. For his own part he had never seen a case of general diffuse septic peritonitis end in recovery.

Dr. A. P. Dudley said with regard to the character of cases that there was less danger when there was pocketing of pus, and this existed in considerable quantity; that the patients most likely to die were those with dirty liquid containing little thick pus. In his opinion, Dr. Grandin would have lost his patient in spite of the serum had he not drained thoroughly.

Dr. H. L. Collyer said that through the courtesy of Dr. Grandin he had seen the case of recovery from the time of operation until convalescence, and it reminded him of those post-mortem cases after laparotomy and sepsis, in which there was a stinking pus the characters of which nobody could mistake. Indeed it had all the different characters of pus seen in the post-mortem room, from a creamy pus to a gray and brown septic fluid. If any case presented a fatal appearance, this one did. To be sure, all surgical means were employed early, but there were some abscesses which could not be opened early on account of being under the intestines. He hoped that by resorting to the serum early they would be rewarded by a reduction of the mortality fifty per cent.

The Chairman said he had used antistreptococcus serum in five cases and all had ended fatally. In looking over a large amount of literature on the subject, he had found that nearly all of the subjects who had recovered gave the following history: High temperature on the third or fourth day after the confinement; stinking discharge, relatively low pulse, symptoms indicative of sapræmia; treatment by curettage, drainage, and use of antistreptococcus serum. But they knew that nearly all of those subjects would recover without the serum. Regarding the nature of the bacteria, he had used the serum in one case, in which bacteriological examination by an expert showed colon bacillus and streptococcus; serum used within thirty-six hours; death within a week; no effect from the serum. In a second case, only the pure yellow streptococcus was present: serum was used within twelve hours in heroic doses, yet acute endocarditis, pneumonia, and hip-joint plegmon developed, and the patient died within the week. Surgeons had reported good results from the serum. Their cases, however, differed from puerperal cases. They could better remove the primary source of infection, and he was convinced that in puerperal cases there was some additional element.

Dr Grandin in his closing remarks expressed his conviction that his was a case of general septic peritonitis. The formation of pus pockets was not against this view. No doubt such pus pockets would be seen oftener post mortem in fatal cases of diffuse septic peritonitis, if the patients had lived long enough. Regarding sponging, he thought no amount of sponging would do any good when pus collections existed everywhere among the intestines. He thought the proper treatment was to open the pockets, and flush, even take out the intestines if time permitted and fold them in a towel containing hot salt solution while thorough cleansing was made. Regarding the value of the serum, he had heretofore lost all of his cases of diffuse septic peritonitis, whereas under the same treatment plus the use of the serum he was enabled now to report one successful case.

Lupus Erythematodes.— Dr. Ehrmann demonstrated at the Vienna Medical Club on November 18, 1896, a case treated by removal of two to three millimetres of the thickness of the skin down to the stratum reticulare cutis. When a layer to this depth only is removed the new formed skin takes on normal healthy features. The speaker had performed the same operation in six instances and no recurrence had taken place. The operation can be done under local anæsthesia with methyl chloride. With one cut an area of four or five centimetres can be removed. Directly after the operation a powder bandage is applied and upon the following day emplast. saponat. salicylicum.

PUERPERAL FEVER IN PRIVATE PRACTICE—DR. CULLINGWORTH'S ADDRESS—STATISTICS—MEDICAL DEFENCE—TEMPERANCE HOSPITAL—SIR B. RICHARDSON'S LATS WORK—MEDICAL DINNER—DR. COLLINS—BOTANIC SOCIETY—DIPHTHERIA—DEATH OF OLIVER PEMBERTON, F.R.C.S., J.P.

LONDON, March 16, 1897.

DR. CULLINGWORTH'S inaugural address to the Obstetrical Society may be regarded as a fitting pendant to his predecessor's farewell address. You will remember that the last utterance, which I duly reported to you, showed what had been done to diminish the mortality of lying-in hospitals. Now, following the pæan on that point, Dr. Cullingworth tells us that the mortality from puerperal fever throughout England and Wales remains undiminished, and he asks how it is that in general practice this condition of things continues. If, as shown the other day in Dr. Godson's address, puerperal fever is practically a thing of the past in our lying-in hospitals, it is impossible now, says Dr. Cullingworth, to ignore the fact that there has not been a corresponding diminution of the disease in private practice. If it was hardly to be expected that those who had been long in practice would at once accept the revolution established by the antiseptic methods, it was to be hoped that when a younger race succeeded a mortality which had been proved to be preventable would show signs of diminution. How is it that this hope has not been realized? Either the profession is not convinced of the possibility of stamping out puerperal fever by the methods proposed, or it has failed to carry them out with sufficient thoroughness. Dr. Cullingworth asserted his firm conviction that by antiseptic precautions conscientiously adopted puerperal fever might be as rare in private as in hospital practice, and he asked some searching questions as to the teaching on this subject in the schools. If the responsible teachers, he said, and he is himself one of them, are not careful to inculcate the necessity of the most rigid antiseptic precautions, their pupils may forget how much depends on minute detail and discharge their consciences by pouring a few drops of carbolic acid, or a drachm of tincture of iodine into the water in which they wash their hands, or even by simply bidding the nurse to administer a similarly prepared solution as a douche. This is no imaginary picture of his, for he declared that many who glibly assert that they use every precaution are content with methods so crude and imperfect as to be a ludicrous travesty of true antiseptic midwifery.

It is nearly nine years since Dr. Cullingworth published a plea for antisepsis in midwifery and he was half disposed to apologize for returning to the subject: but although he found the temptation great to choose a newer topic, he declared that the more he reflected on the matter the more did he feel it a duty once more to raise his voice on behalf of the mothers of this country. He even commended the advice of a female writer on the subject, to the effect that women should satisfy themselves beforehand that both the doctor and the nurse will conscientiously use these safeguards. If puerperal fever is now generally regarded as preventable, it must be admitted that it ought to be prevented, and it is to be hoped Dr. Cullingworth's address will contribute to this consummation.

It is not, however, to be supposed that no protest will be raised as to Dr. Cullingworth's views. In fact, Dr. Robert Rentoul has already challenged them, and seems to regard them as a slur upon or an insult to general practitioners. He gave evidence before the select committee of the House of Commons to show that the statistics of lying-in hospitals are very unreliable, as they really relate only to selected cases, some of the most dangerous classes being ineligible: besides which many women leave the hospitals from seven to ten days after delivery, and are therefore lost sight of. The consequence of this must be that deaths within thirty days of delivery are not all certified, as they should be according to the rules.

Besides this and other points raised by Dr. Rentoul, I am struck by a difference in the statistics submitted by Dr. Cullingworth between the London and provincial figures. In the country he cites mortality, but in London notifications. He says conclusions would come out the same if deaths were counted all round, but that remains to be seen, for certainly the two sets of statistics are not of an identical kind, and the comparison between them may possibly lead to error. No doubt those most interested in the subject will detect this flaw in the argument, and we shall probably be soon flooded with fresh statistics.

The defence scheme of the British Medical Association has received a decided check. The Metropolitan Branch at a special meeting has voted against it. Yet this branch, last year, voted the other way. It is difficult to account for this action, unless it is due to the small number of members who take the trouble to attend. Out of some twelve hundred members an attendance of fifty or sixty is as much as can be obtained. Even on such a momentous question as defence has been held to be by both sides, not a hundred can be gathered together. It is, therefore, less surprising for one meeting to rescind the resolutions of its predecessors. I am assured that a similar state of things prevails in other branches.

The annual meeting of the London Temperance Hospital was held on Monday, the Duke of Westminster presiding. The report stated that eleven hundred and fifty-seven in-patients were received in the past year. The death-rate seems to have been only 7.6 per cent. The death of Sir B. Richardson, who accepted the physiciancy in 1892, was referred to in suitable terms in the report.

By the way, Sir Benjamin's last work, completed only three hours before the apoplectic fit which proved fatal, has now been published under the title "Vita Media: Chapters of Medical Life and Work." It consists of the author's reminiscences of various stages of his life, with reflections of a characteristic kind, and will be greatly appreciated by his professional and literary friends.

On Saturday the Medical Society celebrated its one hundred and twenty-fourth anniversary by a dinner, which was as successful as the many others at these annual gatherings.

Dr. W. J. Collins has been elected chairman of the London County Council.

It has been proposed for the Royal Botanic Society to establish an institution for teaching purposes, such as many foreign cities possess.

The deaths from diphtheria in London have declined, but are still in excess of the corrected average of the week for the decade of 1887-96.

Influenza shows some signs of recrudescence, but the total of deaths from all respiratory diseases is much below the average.

Birmingham mourns one of her most prominent medical sons. Oliver Pemberton died on Sunday, in his seventy-second year, respected and honored by all who knew him. He began his career as a student at the local school and followed that up at St. Bartholomew's Hospital. After qualifying he returned to

his home, passed through the offices at the hospital, became surgeon in 1852, and held the office till 1891, when he resigned to become coroner for the city. In 1886 he was elected to the council of the Royal College of Surgeons. He took a great interest in the public life of his city, and was a justice of the peace for the county. You will remember his "Clinical Illustrations of Cancer," 1867, his "Ingleby Lectures," on the same subject, 1884, and his other surgical productions. He had always felt great interest in medical jurisprudence, and therefore was naturally a model coroner.

HYPNOSIS IN NAUPATHIA.

To the Editor of the Medical Record.

Sir: I wish, through you, to lay before the profession a thought which occurred to me on my last trip across the Gulf; and as I have no opportunity, at present, while thousands are daily presented in your city, of making a test of this idea, I hasten to bring before you what may prove a blessing to the unfortunates who suffer from seasickness.

With a deep sense of the personal equation involved in a case of mal de mer, it strikes me that hypnosis offers a sure preventive, a powerful palliative, or a possible cure for those who go down to the sea in ships.

H. M. Folkes, M.D.

Panzos, Guatemala, February 25, 1897.

THE COMMUNICABILITY OF TUBERCULOSIS AND SPECIAL HOSPITALS FOR PULMONARY CONSUMPTION.

To the Editor of the Medical Record.

Sir: Will you allow a constant reader of your esteemed paper the privilege of contributing a few lines on one of the vital issues of the day? In asking this privilege I would claim that I have made, I believe, a careful study of pulmonary tuberculosis, in its sanitary aspect, for a number of years in this country and abroad.

I have been watching with the most profound interest the controversy now going on between the board of health and the medical profession at large regarding the question of tuberculosis. I have refrained from again expressing an opinion on the subject, for I had defined the position I take in this matter before the Academy of Medicine, on the very evening Dr. Biggs spoke in justification of the action of the board of health, and Dr. Hance described his investigations regarding the infectious nature of dust taken from the rooms of consumptives living in tenement houses.

In all the declarations on the part of individuals or societies thus far published in New York medical papers concerning the subject under discussion, I have not, up to yesterday, found one which was in contradiction to the views I expressed. But when a body of medical men representing an important scientific institution (West Side German Dispensary), to which is attached a medical school for post-graduates (New York School of Clinical Medicine), comes out with statements such as were published yesterday in two of the leading medical papers of this country (New York Medical Record and *Journal*), I think it is time to make a protest; not in the interest of the New York or any other city board of health, but in the interest of science, medical honor, and true humanity, the very things which the medical board of the West Side German Dispensary feels called upon to defend against the intentions of the board of health.

Here is what can be read in its preamble:

"*Whereas*, On January 11, 1897, representations have been submitted to the health commissioners of New York by two officials in the health department, which are inaccurate and misleading in several important particulars and call for an unnecessary and dangerous extension of the powers of the health department, as follows:

"1st. That the statement embodied in the first paragraph of the above report, namely, 'that it is now the universal conviction that tuberculosis is a communicable disease,' is not entirely correct and is not the opinion of many distinguished clinicians."

I fail to see what is the application of the words "not entirely correct." Is there a pulmonary tuberculosis without tubercles and bacilli? Are the experiments of Villemin,[1] Weber,[2] Koch,[3] Tappeiner,[4] Cornet,[5] Krueger,[6] Grancher,[7] Straus,[8] Prudden and Hodenpyl,[9] and many others worth nothing? Have not these men, the highest authorities on the subject, demonstrated beyond a doubt that the tuberculous expectoration, dried and pulverized, floating in the air, is the most potent factor in the propagation of the disease, and that pulmonary tuberculosis is a communicable disease *par excellence*?

I ask the gentlemen who passed those resolutions if they would be willing to expose themselves or their relatives to the inhalation of dried particles of tuberculous dust, or if they would be willing to live with a consumptive individual of whose scrupulous and conscientious cleanliness in regard to his expectoration and other secretions they could not be thoroughly convinced?

To make statements such as are contained in the above-mentioned preamble is certainly a very dangerous thing for a large and influential body of medical men, who have under their care at their free dispensary, no doubt, a large number of tuberculous patients still able to walk about, and each one expectorating daily his millions of bacilli, sometimes into a vessel and sometimes wherever he pleases, since his doctor has declared that it is not the universal opinion that his disease is communicable.

What is written in the medical papers may often be repeated by the daily press. The mind of the public has happily been educated, to a certain degree, to the danger arising from carelessly expectorating consumptives, and we should all willingly and gladly recognize the efficient service done in this direction by the present board of health. If the same public, just beginning to realize how necessary it is to be careful when living with a consumptive, or when afflicted with the disease, should read that the statements previously made to that effect were not entirely correct, all that has been laboriously accomplished in voluntary and public prophylaxis may be suddenly lost, only to be regained after great struggles on the part of the sanitary authorities.

To show that I do not agree with the further statement of the medical board of the West Side German Dispensary that there is no need of special hospitals for consumptives, I will merely repeat what I said

[1] Villemin: "De la Prophylaxie de la Phtisie Pulmonaire," Union Médicale, 1868, p. 150.

that evening when I had the honor to address the academy—that the prophylactic, hygienic, and dietetic treatment of consumptives can be carried out successfully by any physician in private practice, providing his patient is willing, obedient, and socially so situated as to have the comforts and surroundings which the treatment demands. I pleaded for municipal sanatoriums for poor consumptives, and I believe I have demonstrated their need beyond a doubt. Judging from a considerable experience among this class of patients in large cities, I believe I do not exaggerate when I say that I think them the most unfortunate of the unfortunate, and as long as they live in densely crowded tenement houses they not only reinfect themselves constantly but form veritable centres of infection for others.

That our present hospital facilities do not suffice, when the majority of hospitals supported by private charity refuses admittance to consumptives, is too well known to need any further argument, and that most of our general municipal hospitals are ill adapted to carry out successfully the proper treatment of consumptives all those who have studied modern phthisiotherapeutics must certainly admit.

The statistics I gathered for my work on tuberculosis show that in England, where hospitals for the exclusive treatment of consumptives have been in operation for many years, the mortality from tuberculosis has been reduced from twenty-four hundred and ten in a million inhabitants in 1870 to fourteen hundred and sixty-eight in 1893.

In the face of such figures the utility of special hospitals for consumptives can hardly be disputed.

S. A. Knopf, M.D.

THE TUBERCULOSIS QUESTION.

To the Editor of the Medical Record.

Sir: The recent order of the health board of this city requiring the report of all cases of pulmonary tuberculosis has certainly aroused a good deal of adverse feeling in the profession, though unfortunately but little public discussion of the subject from a scientific standpoint. The advocates of the measure appear to have taken it as granted that the profession agreed with them in regarding sputum as the preponderating influence in the spread of the disease, or else determined to force their convictions on the profession before it was prepared by a preliminary education to accept them without protest.

It certainly seems to me that it would have been wiser for those favoring the measure to prepare public and professional sentiment by a careful array of demonstrated facts calculated to sustain their position. Personally I have had but little experience in practical bacteriology, and my clinical experience in pulmonary tuberculosis is but slight. These facts, however, have not debarred me from reading much that has been written on the subject.

That tuberculous infection may occur through the medium of bacilli contained in dried sputum admits of little doubt; but that this is a greatly preponderating influence hardly appears to me to have been satisfactorily proven. The influence of contaminated food has received a certain amount of attention in this connection; the possibility of infection through the medium of ingesta being, I believe, admitted by all. The tuberculin test applied to dairy cows has revealed an astounding prevalence of the disease in certain localities, many herds of milch cattle being found to contain from twenty-five to seventy-five per cent. of contaminated members. The affected animals have been destroyed, the premises have been disinfected, and the disease has disappeared for a time, sometimes to reappear after a longer or shorter interval. It has been generally assumed that the disease has spread through a given herd as a consequence of the introduction of a tuberculous animal; and that the bacilli contained in the secretions of its air passages have been the medium of contagion. Comparatively little attention has been given to what I believe to be a much more frequent cause of contamination. In former times each farmer made his own butter, and if he made more than his family required it was taken to the country store and bartered off for some of the merchant's goods. Except in remote and thinly settled districts this has been pretty much given up, and quite a different system of butter making has been inaugurated. Assuming that the local conditions are favorable for the industry, a creamery is established at a central point, and the milk supply is provided by neighboring farmers. As butter is not made direct from the fresh milk, but only from the cream, two systems of procuring this are practised. Some creameries use "gathered cream" and others procure the cream by centrifugal separation. In this latter case the farmers, usually termed "patrons" draw their milk to the creamery, where it is weighed and then passed through the separator. The cream is reserved for butter making, and the skimmed milk is run into a large vat, which receives the total amount brought during the day or during certain hours. This vat then contains the mixed milk from a number of herds. If now any of the herds are tuberculous, their milk is liable to contaminate the entire contents of the vat. It is the custom for each patron to draw away from the creamery the proportion of skimmed milk that he is entitled to, taking it direct from the vat. This milk he later feeds to his calves and pigs. In a centrifugal separator the milk is poured into a large bowl which is then rapidly revolved, and the cream, being lighter, remains near the centre. The skimmed milk, dirt, and bacilli, being heavier, are thrown outward, and a certain amount of slimy matter coats the interior of the bowl. The skimmed milk and the slime, therefore, contain most if not all of the bacilli. Inasmuch as butter made by the separator process usually brings a higher price than that made from "gathered cream," it is not surprising that the former method has rapidly superseded the other. We can now understand how readily tuberculosis in a single herd may contaminate the calves and young cattle belonging to the dairy herds of the other patrons of the creamery. The heifer calves thus contaminated will in time become milch cows, while the males will be raised for the butcher. This danger has already been recognized by the farmer, and some creameries are reverting to the "gathered-cream" system, as "the much-talked-of tuberculosis makes the raisers of dairy calves uneasy about receiving the milk of different herds" (*Practical Dairyman*, March, 1897).

The report of the Copenhagen Experiment Station states that at a Danish creamery where centrifuge slime was fed to swine, all of these proved tuberculous, and warns against the use of slime for this purpose without its being previously boiled or heated toward the temperature of boiling water. The prevalence of tuberculosis among swine in certain parts of Germany has been attributed to this system of feeding (Woll). Many other examples pointing in the same direction might be quoted.

In view of the facts above stated, it would certainly seem that the bacteriological advisers of the health department have taken quite too narrow a view of the subject, and that broader researches should be undertaken in regard to all of the modes by which tuberculosis may be spread.

There are, I believe, no separator creameries within the jurisdiction of the city health board, but the State board of health could with propriety undertake an investigation of the manner in which skimmed milk is distributed, and propose legislation calculated to diminish the evils referred to. The feeding value of skimmed milk as compared with other cattle food is at the present time about fifteen cents per hundred pounds, and it would therefore be a hardship to compel the farmer to throw it away. Much good, however, could be accomplished if there was a statute forbidding the distribution of skimmed milk to the patrons unless it had been previously boiled, and requiring all separator slime to be burned.

H. G. PIFFARD, M.D.

THE DISPENSARY ABUSE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: May I be permitted to suggest what seems to me a rational remedy for the "dispensary abuse"? After having read in a previous number of the MEDICAL RECORD a rather impracticable mode of ridding ourselves of this "abuse," the following arrangement has occurred to me as simple and feasible. Let the dispensary doctor discriminate between those who can and those who cannot pay. Every man who has done any dispensary work knows how easy it is to do this, not alone from observation, but from what the patients often say unguardedly. Why pay inspectors who cannot do the work properly, when the poor doctor is already provided and can do this sifting process thoroughly? The dispensaries are maintained for what purpose? The relief of the poor. Then, if people are treated who are in a condition to pay, the object is defeated. No dispensary doctor would refuse to treat a patient who he even thought could not pay a physician; those who can pay should not be wanted at the dispensary, and, if they are refused treatment, the object is attained. I contend that the clinics could be purified in this way with no injurious effects. What benefit is derived from statistics showing so many thousand patients treated? None. The injury to the profession is enormous and is increasing, and the evil applies to the younger physicians especially, the very men who are only too glad to get work in the dispensaries that take the bread out of their mouths. From my experience with the doctors who work with me, I can safely say I do not think such a trust as the discrimination between needy poor and those undeserving patients would be abused. Even if it is abused, if a doctor does get a patient to come to his office and secures a fee, that is proof that the pateint does not need the charity so freely dispensed. At the Vanderbilt Clinic, which is maintained for the benefit of the students, the well-to-do patients are almost always those who refuse to enter the amphitheatre or be examined by the classes. They are not too proud to take charity, but are too proud to have their diseases demonstrated. Without exaggeration, between one-third and one-half the patients treated at the above-named clinic are capable of paying a doctor's fee. Why cannot the evil be remedied?

H. H. RODMAN, M.D.

1 WEST SIXTY-NINTH STREET.

Rebellious Neuralgia originating in the eighth posterior cervical root, with pains occupying with marked precision the cutaneous territory supplied by this root, was operated for by opening the vertebral column and resecting the root at fault within the dura mater. The intradural resection constitutes the ideal treatment, the sensitive filaments alone being implicated.—CHIPAULT, *Gaz. des Hôp.*, January 21st.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 27, 1897:

	Cases.	Deaths.
Tuberculosis	194	110
Typhoid fever	8	0
Scarlet fever	225	7
Cerebro-spinal meningitis	5	7
Measles	177	11
Diphtheria	237	33
Laryngeal diphtheria (croup)	15	9
Small-Pox	2	2
Chicken-pox	16	0

The Utility of Sterilization of Milk in some instances is shown by experiments of Schottelius (*Centralblatt für Bakterologie*) proving fresh milk to be an exceptionally favorable medium for the development of diphtheria bacilli, while in sterilized milk the multiplication is much less marked.

A Costly Epidemic.—The rinderpest has been creating great devastation in Bechuanaland, hundreds of cattle dying daily. It is estimated that the cost of the plague before its ravages are over will exceed $25,000,000.

Tweedle Dum and Tweedle Dee.—According to the *Journal of Practical Medicine*, it is wrong for a man to print on his cards "Especial attention given to diseases of the eye and ear," but perfectly ethical to print "Practice limited to diseases of the eye and ear."

A Remarkable Statement.—The animal functions have their nerve supply in the posterior portion of the brain. The brain vaa!raKS?Eelu ,rT p(i-ral,mHffgngrcpl must have room to grow, and not be compressed by faulty position of the infant during its period of development.—*Woman's Medical Journal.*

New York Polyclinic.—The *Dublin Journal of Medical Sciences* makes reference to the faculty of the New York Polyclinic Hospital as a school for practitioners only, where the teaching is clinical and no lectures are given. The critic seems to be of the opinion that this institution has a superabundance of officers. The faculty consists of 30 professors, 14 adjunct professors, 31 lecturers (whose duties are a mystery, as there are no lectures), 24 instructors, and 58 clinical assistants. The hospital contains 70 beds.

Statistics of Medical Men.—Russia with a population of 110,000,000 has only 18,334 physicians, or one to each 6,000 of the inhabitants. In Germany, France, and England, the ratio is one to 3,000, 1,800, and 1,500, respectively. Or, in other words, there are twice as many medical men and women in proportion to the total population in Germany as there are in Russia, and four times as many in England as in Russia and twice as many as in Germany. France having more than Germany, and fewer than England. There are in the United States, with its population of 75,000,000, 120,000 physicians. The European land in which the proportion of physicians is greatest is Scotland. There are, in proportion to the population, more doctors in Ireland than in England, and many more in Spain than in Italy.—*Southern Medical Record*, February.

STRICTURE OF THE URETHRA IN MALE CHILDREN.[1]

BY L. BOLTON BANGS, M.D.,

CONSULTING SURGEON TO ST. LUKE'S, THE CITY, AND THE M. E. HOSPITALS; VISITING GENITO-URINARY SURGEON TO ST. MARK'S HOSPITAL; FORMERLY PROFESSOR OF GENITO-URINARY DISEASES IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE subject of stricture of the urethra in male children is not a new one, for reports of cases have appeared from time to time in the journals and brief mention of the lesion will be found in some of the text-books devoted to surgery and to pædiatrics. The majority of the cases reported has been congenital malformations, either at or near the meatus; others have been described as agglutination of the urethra occurring before birth; and others, again, have been due to traumatism. But the subject of acquired stricture as a result of a post-natal pathological process (other than trauma) has not received deserved attention, for I am led to believe that cases of enuresis and of dysuria in children may be due to this unsuspected cause.

In order to be clearly understood, I beg leave (to quote from my paper on "Stricture of the Urethra and its Treatment") to define stricture as any unnatural narrowing of the urethra in any part of its whole length. At various times attempts have been made to demonstrate the normal urethra as a "closed valvular chink with certain natural or physiological widenings and narrowings in different parts of it." It seems to me that the canal should be looked upon as a living organ, supplied with muscles and nerves for the physiological purposes of carrying away from the body the urine and, after puberty, of ejecting the seminal fluid. Anything in the canal, therefore, that will interfere with the proper performance of these duties or that irritates the nerve relations, disturbs the harmonious action of the organ and must be regarded as pathological and unnatural. Whether it be a deformity resulting from imperfect pre-natal development, or the result of post-natal disease, it occupies the same place in relation to the natural condition of the organ. It is, then, manifest that to arrive at a clear conception of an obstructed urethra its normal state must be appreciated, and, therefore, each urethra must be studied by itself. Observation has shown that these principles may be applied to the urethra of the child as well as to that of the adult. Many of the symptoms in the latter take place in the boy, but with additional features which make the treatment difficult, and, on the other hand, with favorable features, due to the fact that the softer tissues of the child are more amenable to radical cure than those of the adult.

In order that this paper may not extend beyond the limits proper to such an occasion, and in order to define your discussion, it will be devoted chiefly to a consideration of acquired stricture. But, in view of the importance of the subject of traumatic stricture, permit me to call your attention to the fact that there are cases on record of children, from two years of age and upward, who, having suffered traumatisms of the urethra either by blows upon the perineum or by lacerations of the urethra by impacted calculus, have presented later in life symptoms of extreme gravity. Therefore it has seemed to me that the time for treatment of such cases was immediately after the injury, and that, if possible, physiological rest should be obtained for the tissues of the urethra by perineal incision and drainage.

In a paper entitled "A Plea for External Urethrotomy in Minor Traumatisms of the Urethra," I called attention to the necessity for a perinal urethrotomy as soon after the injury as possible, and the abstinence from the passage of sounds and catheters. By perineal drainage nearly absolute rest is assured to the muscles of the perineum, the function of the urethra in most of its length is abrogated, inflammatory complications are prevented by irrigations, and physiological rest for the whole region is almost as nearly obtained as is the case when a splint is applied to a broken leg. The passing of sounds and of catheters through a lacerated urethra interferes with the normal process of repair, irritates the locality of the lesion, and induces an amount of cicatricial deposit which subsequently becomes a source of misery and often of danger to the life of the patient. Even in the youngest subject and in apparently minor traumatisms, I counsel such a procedure, but the anterior portions of the urethra must not be overlooked at the time of the operation.

It is sometimes remarkable with what rapidity evidences of severe and intractable stricture follow an injury upon the perineum of a child, if it is not properly treated. Retention of urine is, of course, often reported immediately; but within a short time after the "apparent cure of the stricture by soundings," incontinence, the formation of fistulæ, and distressingly frequent urination make their appearance.

Not long since I was called to see in consultation a lad of fourteen, who, a year before, had fallen astride a fence, and who had complete retention of urine immediately after the injury. He had been operated upon through the perineum at the time by a local physician, who made the error of not including the anterior edge of the damaged area in the incision. The urethra at the latter point, say half an inch behind the perineo-scrotal junction, had remained strictured; the stricture rapidly narrowed, and from the time of the operation no urine had passed, excepting through the perineal sinus. After some difficulty and in two operations I succeeded in reaching the bladder and in restoring the continuity of the urethra.

In regard to the subject of acquired stricture, it should be observed, first, that the etiology of these cases is often very obscure. In some we are able to obtain a positive and direct history of gonorrhœal infection: in others, vague statements from parents point to some "inflammation" of the parts: while in many no catarrhal or blennorrhagic antecedent condition can be ascertained. From the observation of certain cases of stricture in young adults, I have been led to form the opinion that many of these obscure cases will be found to be due to an extension into the urethra of a balano-posthitis. This opinion, I will ad-

[1] Read February 11, 1897, before the pædiatric section of the New York Academy of Medicine.

mit, is not based upon conclusive evidence, but I have had under my care young adults with the subjective and objective signs of stricture of the urethra who gave a long history of dysuria and of memories from childhood of inflammations about the prepuce, but of no disease acquired from nurse or others.

Of course, it is easy to cast a cynical doubt upon the statements of these individuals and suspect their chastity, but, being interested in the subject and having had some experience in regard to stricture of the urethra in boys, I have been led to make the closest possible investigation with an unbiassed mind and with the determination to arrive at a just conclusion. I have therefore been compelled to believe their statements and to attribute their strictures to a non-venereal source in childhood.

It is interesting to find, from the recorded literature upon this subject, the ages at which boys have given evidence of stricture. Permit me to quote briefly a few cases, with reference especially to the age of the child and also to the etiology:

Dr. Poynter reports a case of a boy, three years old, who was infected with gonorrhœa by a vicious girl (colored) nurse, sixteen years of age. Two years later the child had stricture, which was treated with dilators.[1]

My colleague, Dr. Abbe,[2] reported a case of four strictures of the urethra (three in the penile and one in the membranous portion), requiring external and internal urethrotomy, in a boy three years of age, who had previously been under my care for gonorrhœa acquired from a vicious girl. In this case the gonococci were perfectly distinct, and I treated the boy with weak bichloride irrigations. Six months later, my tour of duty having ended, he came into the service of Dr. Abbe for the relief of retention of urine, which required the operation as stated.

Dr. McMunn reports a case in a child, aged five years, who had had at two years of age a thick, yellow, urethral discharge, lasting ten months. Close questioning failed to elicit a positive cause of the urethritis, but the mother said that the child's nurse had suffered from a yellow discharge at the time. She was sure there was no traumatism. The urethritis was, of course, the cause of the stricture, for symptoms of the affection had existed for three years. There was extreme difficulty in micturition, and the urine was constantly dribbling away. A No. 4 millimetre bougie was firmly obstructed and held at the commencement of the deep urethra. The meatus was ample and the urethra not sensitive. The stricture was very rebellious to dilatation, but, as treatment progressed, a conditional cure was arrived at by means of tapering metal instruments.[3]

In Northrup's American edition of Ashby and Wright's "Diseases of Children" is reported a case of a boy, four years of age, who had always been well previously, who complained of pain in the penis and hypogastrium, and who had dysuria and a discharge from the urethra. The edges of the meatus were glued together and acted like a valve to cause retention of urine. The meatus was incised, the child catheterized and relieved. No opinion was expressed as to the cause of the discharge in this case.

Another boy of five years of age, with a history of discharge for three years, supposed to be gonorrhœa though no microscopic examination is mentioned, is also reported by the same authors. Both cases are looked upon by the reporters as congenital meatus stenosis, but in view of the presence of urethral discharge, especially of long duration, it would have been well to examine the remainder of the urethra. No mention is made of this procedure.

[1] New York Medical Record, November 14, 1885.
[2] New York Medical Journal, December 20, 1890.
[3] British Medical Journal, 1894.

A boy of six years of age, together with an eight-year-old brother, were reported by a Dr. Himowich[1] as cases of probable gonorrhœa. This was stated to be the cause of failure of treatment of "the strictures," no measurements of which are given.

Fleming,[2] in a very interesting article on this subject, reports two cases of impermeable stricture in boys of three and five years respectively, with signs of extravasation into the penis and scrotum. He could give no cause, but suggested that the stricture might have been due to a minute angular calculus which had escaped detection. He reports another case of a child, seven years of age, who for two years had had uneasiness in micturition, a tense, turgid penis, and suffered great agony. There was no hæmaturia. He gives no cause for this case, but concludes, after a very interesting consideration of all the facts, that it was "strumous."

Among other cases of doubtful cause, King[3] reports one of a child who had suffered from early infancy from stricture of the urethra, and who was cured by operation.

The case of a boy of seventeen is reported,[4] who had had gonorrhœa at eleven years of age and again at that time, and who had a stricture in the bulbous urethra of No. 18 Charr. It is interesting to note in this connection that this same author, S. Rona, reports sixteen cases of urethritis, mostly specific, in boys between fifteen months and thirteen and one-half years, but he makes no mention of stricture in these cases.

The case of a boy of eleven, with stricture of the urethra of doubtful etiology, is reported by Bokai.[5] This child had a bad urethritis a year before, followed by symptoms of general syphilis. The child was brought to the physician for the latter disease, and Bokai therefore considered the cause of the stricture undetermined.

Another case in a boy of eleven years, cause not stated, but apparently gonorrhœal, no particulars being given, is reported by E. Desnos.[6]

Another case of doubtful cause is reported by Gärtner.[7] A boy, six years of age, with a stricture of the urethra (location and measurements not given). The dysuria was relieved temporarily by drugs and, relapsing, was treated by catheter. There were hemorrhage and complete retention. External urethrotomy was performed, and the boy recovered with cystitis.

Masturbation has been given as a cause of organic stricture of the urethra. S. W. Gross, in his "Disorders of the Male Sexual Organs" (fourth edition, edited by Sturgis in 1890), mentions a number of cases, notably that of a boy of thirteen years, an epileptic, with a stricture of No. 17 F., at six and one-half inches from the meatus.

Dr. J. W. Thompson[8] mentions the case of a boy of fourteen years with an organic stricture, in his opinion due to masturbation.

In Daniels' *Texas Medical Journal* for March, 1887, a case is reported of a boy, ten years of age, with a history of "spraying" and a small stream since birth. Cystitis was present, and he had three strictures, one posteriorly. The strictures were incised and dilated. This may have been a congenital case, but I agree with Dr. J. William White,[9] who thinks that the history is insufficient and doubts the congenital origin of this affection.

To these cases, derived from a careful search of the literature, for which I am indebted to Dr. Berkeley, I wish to add two in my own experience. I beg leave to report them with some detail, because they may serve as a contribution to the literature of this subject and add to our knowledge of the treatment of the lesion.

Case I.—A boy, three years and five months old, was brought to me by his father with the following history: He had had none of the usual diseases of children, but, on the contrary, had always been strong and healthy and without serious illness until the present one. When about two years of age, he had an attack of diarrhœa, after which he developed a constant pain in the region of the bladder, and on attempting to pass urine it was found that he could pass only a drachm or two in spurts. At first there was no frequency of urination, but as time went on the attempts at urination were repeated frequently, the number of times in the twenty-four hours being indefinite. The efforts to urinate were accompanied by great pain. He would be taken up at night, crying with the desire to urinate, and when placed on the urinal he would sit and strain until a small quantity of urine was discharged. This would be repeated several times during the night. About once in two weeks there would be an exacerbation of these symptoms, during which the amount of mucus and pus in the urine would be increased. During the paroxysms of pain he would cry and seize the glans penis, which suggested vesical calculus, for which he was examined, with negative result.

When brought to me, the child had a robust, hearty, and vigorous appearance in spite of his sufferings. His urine was opaque, extremely alkaline, and putrid. Its specific gravity was 1.020, and it contained about two per cent. of albumin. The sediment was a mass of translucent mucus, many broken-down pus cells, and many small triple-phosphate crystals and bacteria. The symptoms of stone seemed so positive that it was decided that an appointment should be made to anæsthetize him and examine him carefully. In the mean time the condition of the bladder was to be improved by irrigation, etc. This was done by his father, a medical man, a No. 14 F. silver catheter being used. To his surprise, he found that the child's bladder would hold twenty ounces of the irrigating fluid. As may be imagined, the washing was undertaken with great difficulty, the child crying and resisting. Finally, on account of swelling of the penis, the washing was discontinued, and, blood appearing in the urine, the child was brought to me for operation.

He was placed under ether narcosis and a careful exploration of the bladder for stone was made. No calculus could be detected, but the bladder was found to be of large capacity for his age, extending quite up to the child's umbilicus. It was evidently in a condition of overdistention and atony, manual pressure being required to empty it. It seemed to me, therefore, that some obstruction to urination, probably in the urethra, had been operating for an indefinite period to produce this change in the muscular wall of the bladder. Accordingly I explored the urethra, and found a stricture of No. 14 F. just within the meatus. This was incised, and, on inserting the next size bougie à boule, viz., No. 15 F., it was distinctly obstructed by two stricture bands, one one and one-fourth inches and the other two inches from the meatus. They were not tough or fibrous in structure, but apparently soft and yielding, so I thought it well to test the question of their cure by dilatation. The meatus was still further divided to No. 20 F., and the bladder was emptied and irrigated. No untoward symptoms arose, and the father was instructed to continue the emptying of the bladder by means of the catheter and to leave the dilatation to me. The latter was persevered in by the passage of soft instruments up to No. 20 F., and the condition of the child gradually improved, the blood disappearing immediately after the relief of the overdistention of the bladder. The latter gradually regained its power, the frequent and painful urination ceased, and the urine assumed a more natural condition. I have not seen the child in two years, but recently I received a letter from his father, who says: "It is with pleasure that I can report him normal as to urination. He does not have the least trouble, so far as we know. There is absolutely no pain. He urinates on an average four times daily, and almost never gets up at night for the purpose. He is developing, we believe, evenly in all directions."

The etiology of the strictures in this case is evidently obscure. I could obtain no history of urethral discharge, but on closely questioning the mother I learned that in his early infancy he had some form of "skin eruption" and some irritation of the prepuce, which was very redundant. The latter had been "dilated" from time to time by means of pocket forceps, for at the time he seemed to have some dysuria. How much importance to give to these symptoms I am in doubt, but in view of the statement in regard to the foreskin it is possible that he had a balano-posthitis which subsequently infected the urethra. Although this is problematical, the conclusion seems warranted that, as he was apparently a perfectly healthy child from birth up to the onset of the painful urination, it was a case of acquired urethral stricture and not due to any condition before birth. The blood in his urine just prior to the operation was an interesting feature. At first it was dark in color, was intimately mixed with the urine, and there were no clots. Subsequently it became bright and clotted, and sometimes merely tingeing the urine. At the time of the operation I injected eight ounces of clear boric-acid solution into the bladder, and after manipulating the right kidney and ureter withdrew twelve ounces of a bloody effluent. The same procedure on the left side produced only the amount which had been injected. I drew the conclusion that there had been a dilatation of the right ureter and pelvis, but this may be only speculation and I have no positive explanation of the symptom. At all events, the blood suddenly ceased when the bladder was relieved.

Case II.—The second case was that of an intelligent lad of fifteen, who gave me the following history, supplemented by statements from his father: For some years (the time could not be definitely stated) the boy had had considerable trouble in urinating; that is, his urine when passed would scald him, and whenever he "caught cold" the act of urination was accompanied by pain. When thirteen years of age he had an attack of complete retention of urine, to relieve which he was given ether and a catheter was passed. It was necessary to repeat this operation, aided by an anæsthetic, each day for a week. In the second week it was done every third day. As he had a long foreskin, this was considered the cause of the retention, and he was circumcised. After that he was etherized and catheterized "a couple of times," then was given some internal medication, and finally got so that he could urinate with but little pain. Following the catheterizations he had a discharge from his urethra, which was described as greenish-white and which stained his clothing yellow. This discharge persisted for nearly a year and a half, when a doctor prescribed an injection for him which was used twice a week, with the result that the discharge ceased and he found himself able to urinate with more comfort. Still, if he had what he called "a cold," he immediately had a return of the difficult and painful urination. At times he had had a thin watery discharge from the urethra.

To quote from the record made at the time: "At present he has no frequency of urination. According to his statement, he urinates but 'three times' during the day, usually once during the night, and sometimes he will go for a period of three weeks without any nocturnal urination. On examination the urinary organs appear to be normal. The discharge described in his history is not now present. He urinates in my presence in a fine, dribbling stream with straining, and evidently it requires considerable effort to empty the bladder. Examination of the urethra shows a stricture of No. 10 F. a short distance within the meatus. The locality is excessively sensitive and further examination is impossible. It is therefore deemed advisable to put him under an anæsthetic, explore the urethra thoroughly, and do whatever is determined by the examination."

Accordingly, after antiseptic preparation, he was anæsthetized, the meatus and the first stricture were divided to No. 26 F., and then three distinct, tough, fibrous bands of No. 12 F. were found between the meatus and a point two and three-fourths inches from the latter. The remainder of the urethra was normal. These bands were divided by the Maissonneuve urethrotome, followed by the Otis dilating urethrotome, until a No. 26 F. bougie à boule passed smoothly and easily. On the following day, under primary ether narcosis, a No. 26 F. bougie was passed, and subsequently the sound was passed once in four or five days. Two weeks later he was sent home to his doctor in the country, with directions to pass the sound once a week until all bleeding ceased, but not to pass any instrument if the urethra was irritated or inflamed by its use. A recent inquiry in regard to this patient, of the medical friend who sent him to me, elicits the information that the boy has remained perfectly well, urinates without trouble, and thus far has shown no evidence of recontraction.

Again I am compelled to admit the doubtfulness of the etiology. It is true there is no history of infection by nurse or others, and no history of balano-posthitis could be obtained; but as these strictures were firm and fibrous, such as follow urethritis in adults, it seems to me that the etiological factor must have been forgotten and that in all probability it related to the prepuce. The only urethral discharge referred to in the history was probably due to infection from the repeated catheterizations. No examination of it was made, and I was unable to make any because there was none present when he came to me: moreover, speedy relief was imperative, and therefore the operation was at once undertaken.

You will observe the difference in the severity of the symptoms in these two children. The younger child, although his urethra was not so much strictured relatively as was that of the older boy, had the most violent symptoms and suffered far more, and yet regained with remarkable rapidity the tone of his bladder. You will observe also the contrast in the treatment. In one case, the strictures being soft and yielding, a good result was arrived at by intermittent dilatation; while in the other it seemed to me better judgment to apply the principles of internal urethrotomy to secure, if possible, a radical and permanent cure.

What the permanent results will be in these cases I am unable to say, but it is my intention to keep them under observation and to obtain from time to time re-examinations of the urethra. At present they are both beyond my reach, and I am able to report only the statements as to their general well-being.

Army Dentists.—The Ohio State Dental Society has voted to petition the government to appoint dentists for regular service in the army.

FLUOROGRAPHY FOR DETERMINING THE POSITION, SIZE, AND MOVEMENTS OF THE HEART.[1]

By THOMAS E. SATTERTHWAITE, M.D.,
NEW YORK.

THERE has always been some diversity of method in mapping out the heart. But the recently revived interest in the treatment of chronic heart disease has stimulated some of us to devise new methods promising greater accuracy. Most of the work, however, has been confined to radiography, or getting shadow pictures by means of the photographic plate; but these results have not been altogether satisfactory, for several reasons. One of them is that the radiograph requires more or less prolonged exposure to the Crookes tube, varying from one minute to forty minutes or more; while during this period the alternate movements of the heart cause the picture to represent, so far as the outline is concerned, only the fullest expansion of the organ. Besides, owing to the divergence of the *x*-rays as they pass over the edge of the opaque heart, that organ is still further magnified. This matter will be alluded to again farther on. A better idea, however, of the heart, is obtained by the unaided eye. For, if a silhouette of the organ is thrown on the fluorescent screen in a darkened room with a cap over the Crookes tube, the relative position and movements of the organ can be observed with considerable ease. But it is not so easy to register them accurately on paper.

So far as I know, indeed, the first effort made in this direction was by Dr. H. Campbell Thompson, of the Middlesex Hospital, London. In a letter published in *The Lancet* on October 10, 1896, and in an article in the same journal on December 12, 1896, he described a "practical application of the Roentgen rays in diseases of the heart and great vessels," stating that the size and shape of the heart could be estimated by means of the Roentgen rays and a fluorescent screen, and also that with a little trouble a tracing of the heart could be obtained. I have conducted a series of experiments in the same line and have verified many of Dr. Thompson's statements, while others I have not found tenable. Dr. Thompson states that when the focus tube is placed behind the person, so that the rays pass through the thorax, (the fluorescent screen being presumably placed on the patient's chest), the bones are very clearly marked out, while the heart is seen as a definite shadow in contradistinction to the light area around it. He further adds that not only can the outline of the heart be clearly seen but its pulsating movements detected. He also observed the rise and fall of the diaphragm. These are important points, and of some clinical value, for what we need especially at the present time is a view of the borders of the heart, and particularly its lower line, which is practically determined by the level of the diaphragm. Now the heart can be seen when the screen is placed on the patient's chest or on his back, but the silhouette is best when the screen is placed on the chest. The three illustrations that accompany Dr. Thompson's article admirably illustrate in a diagrammatic way the silhouettes that he saw, but unfortunately no such pictures are actually obtainable, for the ribs and other bones of the thorax, which he shows as encircling the heart, are not usually seen and did not appear clearly in any cases that I have seen; or, if they appeared at all, darkened the picture so that the heart was quite invisible. For ordinarily the bones are quite invisible when the heart is brought in clear relief, the spine alone showing itself. Dr. Thompson's pictures of the heart are also of nor-

[1] Read before the Section on general medicine of the New York Academy of Medicine, March 6, 1897.

mal size, while in reality they should have been considerably magnified. In fact, if the Crookes tube is placed opposite the centre of the heart, which usually corresponds to the left transverse process of the seventh dorsal vertebra, the outline of the heart as thrown on the screen should be magnified from one-quarter to one-third, owing to the divergence of the rays as they pass over the borders of the opaque heart. The nearer the heart to the tube, of course the greater the distortion.

Dr. Thompson's method is as follows, briefly: His patient stood before the tube with the screen on his chest. The tube was placed against the left transverse process of the seventh dorsal vertebra, and the whole outline of the heart on the screen was then seen by the naked eye. The edges were shadowy, but still they could be outlined and a pulsation of the chambers clearly seen. Indeed, when the heart is magnified in this way, the excursions of the chambers are seen to unusual advantage; but, as the adjacent landmarks formed by the ribs and sternum are not distinctly seen, the picture is unreliable and useless for ordinary clinical purposes.

The method which I call *fluorography* is destined to overcome this difficulty, reducing the silhouette of the heart to its actual size. My routine is as follows: I make a map of the heart on the anterior chest wall; then I mark on the back with a dermographic pencil the angles of the heart, taken from a pattern of the map, either taking the seventh verebra for a centre, or, which is better, placing the apex and other angles on the same level and in the same relative position behind as in front. Then I apply the Crookes tube to each successive point behind and the silhouette will be found to correspond closely with the outlines of the heart as mapped out by percussion. But it will be more satisfactory. Skilful percussion marks out accurately the curved line of the right side of the organ. It also shows the left side by indicating the border from the sternum diagonally downward and outward; but it often fails to give the contour in the vicinity of the apex, and does not give the lower line. To gain accuracy in this method you may have to use a cardiometer and a level, or chest callipers, so that each angle behind is brought precisely opposite each angle in front and in the same relative position. Now attach a piece of tracing-paper, with rubber bands, to your fluorescent screen and bring the Crookes tube to bear against the several angles of the heart: as the tube passes from angle to angle, you may be able to note two lines, corresponding to the limits of contraction and expansion of the heart. Connect the outer series of these lines and then the inner series. Then note the level of the diaphragm. Carry your pencil along this line and you have the lower line of the heart. In this way you have a fairly accurate tracing of the heart both in contraction and expansion, and you may now compare it with the outline as mapped out by percussion on the skin of the chest. Even allowing for slight movements of the screen and the inexperience of a draughtsman working in an unusual light, you find that your fluorograph and the map drawn on the skin are wonderfully in agreement, but the former is more complete. If, however, you need a silhouette with the natural landmarks, you have to adopt another method which is a little tedious. First, make a tracing of the chest on tissue paper, showing the two nipples, the episternal notch, ensiform cartilage and the ribs and sternum or intercostal spaces. Mark these landmarks with the heaviest tin foil, say from one-eighth to three-eighths of an inch wide, and fasten them down to your tracing paper with rubber plaster. You have now a mask of the chest. Apply it accurately, sternum to sternum, rib to rib, and fasten it in place by broad bands of rubber plaster. Now make a separate tracing of the chest. This you apply to the fluorescent screen with rubber rings: next apply this tracing and screen to the mask, landmark to landmark, and when the focus tube passes round the heart you mark on the tracing-paper the several angles of the heart, and if conditions favor you have a register of the size, position, and excursions of the chambers with their natural landmarks. This you can now put away in your case book for future reference, and you have a guide by which you can note any change in the form of the heart as the result of your treatment.

But the advantages of this latter plan are more or less offset by its disadvantages. It is true that you have the landmarks plainly in view, but they to some extent cut off the light and therefore make the outlines shadowy. Therefore the strips of tin foil should be quite narrow, your tube of the best, as also your screen. Nor can this method always be applied; when the chest is deformed, the sternum is bent, or the lower ribs are crowded together, it may be impracticable. In such case, a simpler plan is advised. Run a strip of tin foil of heaviest make, not wider than three-eighths of an inch, possibly less, down the centre of the sternum. Fasten it with rubber plaster. Run a similar strip from nipple to nipple; attach this also. Then run two similar strips vertically through the nipples, or on the line of them: attach them with plaster. These rectangular lines may prove to be landmarks of sufficient accuracy.

It is pretty generally known that various plans are in use for mapping the heart, adapted to the skill of the physician in percussion. Some are able to outline the extreme borders of the heart with great accuracy; others are not, and fall back to taking flatness as the guide to the heart's dimensions. Now, these areas of flatness as a rule fall more or less within certain artificial right-angled triangles. Of these cardiac triangles there are two, the larger including the smaller. The larger triangle has for its vertical side a line let fall perpendicularly from the episternal notch; for its base, a horizontal line drawn to meet it from the upper border of the sixth costal cartilage at its junction with the rib. Both vertical and horizontal lines are of the same length. The hypothenuse connects their extremities, meeting the vertical line at the upper border of the second costal cartilage; the apex of the heart is supposed to be at the junction of the base line and hypothenuse. The lesser triangle is formed of the same vertical and same base line, but the hypothenuse, leaving the vertical line at the level of the third costal cartilage, passes downward and parallels the other hypothenuse. The areas of dulness and flatness are supposed to be found within the larger triangle, flatness within the smaller triangle; but in reality this is not so, and flatness is of course no proper guide for the dimensions of the heart. These flat areas change with every breath, as the to-and-fro movements of the lungs alternately diminish and enlarge them. Another class of practitioners do not attempt to delimit the heart, but simply indicate by vertical lines the extreme right border and extreme left border and apex. In women and in stout people there is of course manifest difficulty in all these matters, but fluorography shows that in a male of ordinary build the heart can be mapped out accurately in its entire contour up to the origin of the great vessels; while in stout people it may be seen with sufficient clearness to warrant a belief that with improved appliances and a better current any heart can ultimately be fluorographed. Still this fluorographic method is, I believe, capable of achieving more accurate results than any other at present in use, if used with skill, proper appliances, and the necessary precautions: so that there is a strong probability in my mind that fluorography will at some future time be

used to map out the heart for ordinary clinical purposes. At the present moment this method has a special interest because our remedial agencies in chronic heart disease are chiefly directed toward contracting a dilated heart, and if a Crookes tube can be made to throw an accurate picture on a screen we have a new and reliable method of determining whether a given line of treatment is accomplishing any good result or not.

In conclusion let me emphasize the point that I am not at present prepared to state that fluorography will supersede percussion in mapping out the heart; though I can conceive that the size, position, and measurements of the heart *may* be determined by fluorography without either percussion or auscultation. But, given the position of the apex and a few more prominent points in their relation to the anterior chest wall, and fluorography will define the rest, giving us a more complete outline of the heart than any other method known to us.

504 Fifth Avenue.

THE SERUM DIAGNOSIS OF TYPHOID FEVER.[1]

By C. A. ELSBERG, M.D.,

assistant pathologist, mt. sinai hospital, new york.

Up to the present time, the diagnosis of typhoid fever has been based upon the presence of a number of signs, *e.g.*, characteristic temperature, enlarged spleen, roseola, etc.—signs which vary considerably both as to the time of their appearance and the duration of their presence. In the search for a more rapid diagnostic method, most of the work has been in the direction of the discovery of improved means for the differentiation and recognition of the specific cause of the disease, the typhoid bacillus. The difficulty which has been encountered is that the bacterium coli commune, which is to be found in every human intestine, normal and pathological, has no known qualities by means of which it can be differentiated with certainty from the typhoid bacillus. A little more than a year ago, Elsner[2] recommended that one per cent. of iodide of potassium should be added to the medium used for the cultivation of the typhoid bacillus. In an acid nutrient medium of potato gelatin, to which has been added one per cent. of iodide of potassium, only the typhoid and the colon bacilli will grow, all other organisms being inhibited. The colon bacillus grows more rapidly than the typhoid bacillus, so that in twenty-four hours the colon bacillus will already form small colonies appreciable to the naked eye. After forty-eight hours at room temperature the colon bacillus forms large colonies, while the typhoid bacillus forms small colonies. A number of observers have, however, found that some of the small colonies may consist of the colon bacilli; hence the test may often fail. If one makes a mixture of colon and typhoid bacilli and inoculates the same on Elsner's medium, the typhoid bacillus will sometimes not grow at all. These facts have caused us, as well as a number of other observers, to give up the use of Elsner's method, although the knowledge that we can isolate the colon and typhoid bacilli from all other organisms by this means, constitutes a distinct advance in bacteriological methods.

The Widal reaction is based on an altogether different principle than that just mentioned, depending upon the changes that occur in the blood of patients who have or have had typhoid fever. While one generation ago the study of the cell was occupying the attention of investigators, in the last decade a great deal of attention has been paid to the body fluids and, above all, to the blood. Numerous careful studies have been made of the changes in the blood as brought about by disease. Yet we must always remember that, however great the changes found in the blood, these changes are the direct and final result of cell activity, and that in this way blood pathology and cellular pathology are inseparably connected.

A study of the human blood has shown that it contains, under normal and under pathological conditions, substances which act to protect the organism against the invasion of bacteria. In the first place, the blood serum contains substances which are directly antagonistic to germ life. These substances, the alexins of Buchner, have been found in healthy human and animal blood serum, but are present in considerable quantities in the blood of human beings or animals that have acquired natural or artificial immunity against some particular disease, the alexins in this latter case acting powerfully against the bacteria that caused the disease in question. Thus Buchner found alexins in the blood of healthy men; two French observers' described alexins against the bacillus pyocyaneus, the bacillus of green pus, in rabbits that had been rendered immune to this organism.

In the second place, the blood contains substances which act against the poisons produced by the bacteria. These are the antitoxins, and for a large part of our knowledge concerning them we are indebted to Behring. Russian and German observers[2] have found antitoxic substances in the serum of healthy persons. These antitoxins, however, act against the poisons produced by all bacteria, and seem to be altogether different from the specific antitoxic substances found in the serum of an animal or human being immune to a particular organism. That antitoxins and alexins are not identical has been beautifully shown by Behring, when he demonstrated that the strongest diphtheria antitoxic serum, of which the smallest part of a drop suffices to neutralize what is otherwise a poisonous dose of a culture of the diphtheria bacillus, this same serum is a very good culture medium for the Klebs-Loeffler bacilli.

In the third place, if the blood serum of an animal protected against a certain organism is injected, together with a virulent culture of the organism in question, into the peritoneal cavity of a normal animal, and at intervals the peritoneal fluid be examined under the microscope, the bacteria are found to undergo rapid degenerative changes. They become granular, swell, break up, and gradually become dissolved in the serum. These changes are brought about by the bacteriolytic substances that were contained in the blood, substances for which Fraenkel[3] has recently proposed the name "lysogenic substances." This "lysogenic" power of the blood has formed the basis for Pfeiffer's work on the specific cholera immunity. Pfeiffer[4] injected the serum of guinea-pigs which had been rendered immune against the experimental cholera infection, together with what was otherwise a fatal dose of cholera culture, into the peritoneal cavity of healthy guinea-pigs. By means of small capillary pipettes, he withdrew at short intervals small quantities of the fluid from the peritoneal cavity. On microscopic examination of this fluid, he found that the bacilli, that had previous been moving rapidly, became clumped together very quickly, and soon underwent degenerative changes. This reaction Pfeiffer

found to be an absolutely specific one; that is to say, the cholera serum had this effect on the cholera vibrio and on no other organism; and he offered this "specific cholera reaction" as a method for distinguishing the cholera bacillus from all other organisms. Pfeiffer[1] and several other observers then found that the clumping of the bacilli took place to the same degree when serum and culture were mixed outside the animal body, in the test tube. Later, Pfeiffer and Kolle[2] showed that typhoid serum had the same selective action for the typhoid bacillus as had the cholera serum for the cholera vibrio.

In this manner, then, it was demonstrated that just as there were specific alexins, specific antitoxins, and specific lysogens, so there were also specific clumping substances or "agglutinins" in the blood. The clumping or agglutination had, however, been described some years before Pfeiffer's publications by a number of observers working with a number of organisms. Thus, in 1889, Charrin and Roger[3] published an account of their researches on the agglutinative action of the sera of animals rendered immune to the bacillus pyocyaneus, and in 1894 two Russian observers[4] described their experiments with the vibrio Ivanoff. To Gruber and Durham,[5] however, we must give the credit for the first careful description of the phenomena of agglutination. When the serum of an animal immune to typhoid infection is added to a bouillon culture of the typhoid bacillus, the diffuse moirée cloudiness of the bouillon gradually disappears. The bacilli form small clumps, at first adhere to the sides of the tube, and then gradually sink to the bottom, leaving the bouillon above perfectly clear. To this process of clumping Gruber applied the term "agglutination." In his researches Gruber showed that the blood serum of patients that had just had typhoid fever gave the same reaction as did the serum of immune animals, and hence he considered this a reaction of immunization. This, then, was an excellent method of ascertaining whether a patient had just had typhoid fever, by determining whether he had in his blood serum the specific agglutinating substances against the bacillus of Eberth. Widal,[6] in June of last year, then showed that this agglutinative action might be found as early as the first week of the disease, and that the reaction was one of infection and not of immunization. As a result of further researches, Pfeiffer and Kolle then declared that the agglutinins were in no way related to the immunizing substances, and thus agreed with Widal.

Widal obtained the blood of typhoid patients by withdrawing blood from a vein of the arm by means of an aspirating needle. The blood was allowed to clot, and the serum thus obtained was used. Eight drops of this serum were added to four cubic centimetres of a twenty-four-hours old bouillon culture of the typhoid bacillus. In periods varying from three to twenty-four hours, the bacilli became clumped and gradually fell to the bottom of the tube, leaving the fluid above quite clear. Or, he added the serum to a fresh-bouillon tube, and then inoculated the mixture with the typhoid bacillus and kept the tube at 100m or body temperature. After twenty-four hours this tube presented an appearance similar to the first. Or, in the third place, he declared that one might add one drop of the serum to ten drops of the bouillon culture, and then examine a drop of this under the microscope. The bacilli become immobilized and clumped at once or in periods varying from a few minutes to twenty-four hours. Widal recommended a dilution of 1–10 in this last method, because in a dilution of 1–2 or 1–5 he sometimes noticed slight clumping when he used normal serum. After Widal, Fraenkel,[7] Délepine and Sidebotham,[8] Grunbaum,[9] Haedke,[4] Breuer,[5] Kolle,[6] and numerous others published reports of observations made with the test-tube method. One difficulty in the tube test, however, was that it necessitated a considerable quantity of blood serum, which it was often difficult to obtain. Widal, Délepine,[7] Fraenkel,[7] and others then recommended the microscopic test, most of the writers advising that the blood be obtained and preserved in capillary tubes which were sealed by heat after they had been filled with blood. In general use, however, capillary tubes are apt to be broken, both in obtaining the blood and in preserving the same; hence methods such as that of Délepine are not practical. Wyatt Johnston,[9] of Montreal, then proposed that dried blood should be used for the test. Widal had in his original communication declared that he had obtained the reaction from dried serum. All that was necessary, according to Johnston, was that a few drops of blood derived from a clean finger should be allowed to dry on a slip of sterilized paper or a glass slide, and this then sent to the laboratory for examination. Little work has as yet been done with this method. Johnston and McTaggart, of the Montreal board of health, Biggs and Park,[10] of the New York health laboratory, and Pick,[11] of Vienna, are the only ones who have made careful studies of the dried-blood method. The observations on which this paper is based were made to a large extent with dried-blood specimens.

The finger was well cleansed with ether, was then pricked with a needle, and a few drops of blood thus obtained were allowed to dry on a clean glass slide. With a platinum-wire loop one millimetre in diameter a drop of sterilized water was added to one of these dried drops of blood, and the blood dissolved by rubbing with the loop or by allowing the water gradually to soak up the dried blood. A loopful of this is mixed on a cover glass with three loopfuls of an eighteen to twenty-four hours old bouillon culture, or of an emulsion of a twenty-four-hours-old agar growth. This is then examined as a hanging drop. The bacilli, which previously were moving across the field with rapid motion, are found to have become immobilized and clumped together in a peculiar loose characteristic manner. There is usually absolute cessation of movement at once, so that all motion has ceased by the time the slide is placed under the microscope. There often remains a slight struggling motion, just as if the bacilli were bound to each other by their flagella, the cell bodies being free.[12] I have attempted to stain the clumps of bacilli in order to examine the appear-

[12] When the dried-blood solution contains many small masses of fibrin, the bacilli will often cling to these, thus forming clumps and giving a pseudo-reaction. A number of moving bacilli always remain, however; and besides, with a little care one can always recognize that these clumps consist mainly of fibrin.

ance of the flagella, but thus far have been unsuccessful, as the presence of the serum presents a number of technical difficulties.

At times the bacilli do not all become clumped at once; the clumping may be delayed, the bacilli simply being immobilized at first. In the large majority of cases the clumping is complete at once. In some cases it is delayed for some minutes, or there are still a few moving bacilli. I believe that for a positive reaction the agglutination and cessation of movement must be complete in less than fifteen minutes, usually in from two to five minutes. Whenever I have waited longer than this, I have been in doubt as to the reaction. It is a very interesting fact, also, that a beautiful reaction can often be obtained when one uses a culture of non-motile or even dead bacilli.[1]

Inoculation of a fresh agar or bouillon tube, from a reaction in the test tube or from a microscopic reaction, will always give an abundant growth of bacilli, showing that in the reaction these are simply inhibited in their growth and not killed. Indeed, after forty-eight to sixty hours the reaction in the tube will disappear, the bacilli again begin to grow, and such a tube after five or six days will present almost the same appearance as any five or six days old culture of the typhoid bacillus.

On examination of the reaction in the hanging drop after several hours, one can often see that the clumps of bacilli are undergoing degenerative changes. They become pale and swollen at their ends, and then break into pieces. This phenomenon has seemed to me to occur most often when solutions of the entire blood are used, as in the dried-blood method. This fact has also been noted by Johnston and McTaggart.

In order to determine whether the dried-blood method was anyless certain or delicate than the fluid-serum or the macroscopic tube test, I have made the following comparative examinations: Thirty cases were examined, of which number sixteen had typhoid fever, and fourteen were suffering from other febrile diseases. Of the specimens from the patients with typhoid fever, seven gave no reaction when examined by either the dried-blood, the fluid-serum, or the test-tube method. All these specimens were taken from patients early in the disease. The remaining nine cases gave a positive reaction with all three methods. Of the fourteen non-typhoid patients, not one gave any reaction with either of the methods. To judge then from these examinations, few as they are, one would say that the dried-blood test was as certain as the other methods. In addition, in several cases in which the reaction did not appear until late, I made the tube test in the hope that the reaction might be present in the tube when it was not present in the fluid-serum or dried-blood microscopic tests. But in every case in which there was no reaction with dried blood there was no reaction with fluid serum.

It is true that the dried-blood method does not allow of accurate dilution, the importance of a sufficient dilution having been mentioned above. A little calculation will show that a dilution such as I make must be at least 1–8. And as in this dilution I have not been able to note any clumping with normal serum, it seems to me that for general use the dried-blood method with this dilution would be a practical and generally useful test.

In the examinations I made use of bouillon cultures of Eberth's bacillus from twelve to twenty-four hours of age, or emulsions of agar growth of the same age. I have found no advantage in the blood-serum growth as recommended by McWeeney.[2] Fresh agar tubes were inoculated every fourteen days, and daily cultures on neutral bouillon or agar were made from these.

Three cultures were used in my work. Two were of a low grade of virulence, as tested on the guinea-pig according to Pfeiffer's standard. Both animals remained well after the injection, their blood showing a good agglutinative action after five days. The third culture was one of high virulence, one-fifth of a milligram of a moist agar culture being sufficient to kill a guinea-pig of three hundred and twenty grams weight in about sixty hours. I found the two attenuated cultures to give the best results.

Regarding the dilution in which the serum is still active, I have few data. In four cases, the reaction was still present in a dilution of one part of serum to one hundred of culture; in one of the specimens it was still present in a dilution of 1–200.

When the albuminoid substances are removed from an active blood serum, the serum loses its agglutinating power. Widal declares that the serum albumin contains no agglutinins, but that the fibrinogen, the globulins, and the leucocytes contain considerable. The agglutinins are dialyzable, and both this and their easy solubility would point to their being perhaps crystalloid in character. The agglutinins are to be found not only in the blood but also in the saliva, tears, urine, blister fluids, bile, milk, and slowly appearing inflammatory exudations. Achard has found in two cases that the blood of infants, born of mothers who had or had just had typhoid fever, gave a good reaction.

Our experience extends over a series of four hundred and ten observations. Of these two hundred and sixty-two were made on patients with typhoid fever and one hundred and forty-eight on patients with other febrile diseases or in health. Owing to an epidemic among the nurses in the training-school connected with the hospital, I have been able to make a number of repeated examinations early in the disease. Specimens of blood were examined daily until the reaction appeared, and once a week thereafter. I must here express my acknowledgment to Dr. N. E. Brill, the attending physician, for the interest he evinced in the work, and the assistance he gave me in obtaining specimens, as well as to the members of the house staff of Mt. Sinai Hospital.

The two hundred and sixty-two examinations were made in thirty-six cases of typhoid fever. The reaction appeared:

In	1 case	on the	4th day.
"	2 cases	"	5th "
"	20	"	7th–12th day.
"	8	"	12th–14th "
"	2	"	14th–17th "
"	3	"	24th, 27th, 32d day, respectively.

Thus we see that in eight per cent. of the cases the reaction was present in the first week of the disease: in eighty-six per cent. it appeared before the end of the second week; and in fourteen per cent. it appeared after the fourteenth day. In no case in the series did we miss the reaction, but I can well understand how those who made but one or two examinations have reported cases without reaction.

In general the reaction appears suddenly, it being absent on one day and marked on the next, though for several days before the reaction appeared and after the reaction disappeared I have often noticed slight clumping.

The reaction may persist for only a short time: thus in one case the reaction disappeared in eight days, in another case after twelve days. The reaction may disappear soon after convalescence begins: thus in one case it disappeared at the end of the fifth week. In the large majority of cases, however, it

[1] A French writer has recently proposed that one keep stock tubes of bouillon cultures of the typhoid bacillus that have been killed with formalin for the test, thus to obviate the necessity of daily reinoculation of the cultures.

[2] McWeeney: Lancet, December 12, 1896, p. 1,717.

persists for at least several months after the disease has run its course; thus of the thirty-six cases of typhoid in our series, the reaction disappeared in one case after the fifth week; in two cases three weeks after convalescence; in eight cases the reaction was still present when the patients were discharged one month after convalescence.

Of the twenty-two cases still under observation, in all the reaction is still present, periods of three weeks to two months since the disease. In one patient, who had typhoid fever five months ago, the blood still shows a marked reaction. This patient has had an osteomyelitis of the inferior maxilla since four months, perhaps due to the typhoid bacillus, and this may have been the cause of persistence of the reaction.

Thayer,[1] of Johns Hopkins Hospital, offers a similar explanation in a case of "typhoid osteomyelitis," in which he found the reaction sixteen months after the attack of typhoid fever.

Three patients of our series died, and in all three the characteristic lesions were found at the post-mortem examination. I found no reaction in eight individuals who had had typhoid fever from six months to ten years ago.

Of the thirty-six cases, four had relapses, one of these having two relapses. Of these four cases, in one the reaction appeared on the sixteenth day, and remained throughout the disease and relapse up to the present time. In the other three cases, the reaction appeared late—on the twenty-fourth, twenty-seventh, and thirty-second day, respectively, of the disease—and disappeared again on the thirty-sixth, forty-second, and forty-eighth day. In two of these three cases, the reaction again appeared on the fourth day of the relapse. In the third case the reaction did not appear in the relapse, but the patient had a second relapse, on the fourth or fifth day of which the reaction again appeared. Here then we have three cases. In two there was incomplete immunization, as shown by the occurrence of a relapse, and brief presence of agglutinins, as shown by the short duration of the reaction. The third case is still more interesting. In this there was incomplete immunization, and small amount of agglutinins during the attack. The patient then had a relapse, but was not yet sufficiently immunized, nor were there sufficient agglutinating substances present in the blood to give a reaction. It was only in the second and last relapse that the reaction appeared. I recognize that these cases are too few for me to draw any conclusions from. However, they are so striking that one cannot but suspect that the agglutinins are in some way related to the immunizing substances in the blood.

I have not been able thus far to find any relation between the severity of the attack and the time of appearance and duration of presence of the reaction. In fact, in several of the severest cases we have seen the reaction appeared late.

Of the one hundred and forty-eight patients whose blood was examined, who were well or were suffering from other diseases, in one hundred and forty-seven the reaction was absolutely negative. Among these patients were cases of bronchitis, pneumonia, influenza, intermittent fever, colitis, pleurisy, phthisis, cystitis, rheumatism, nephritis, endocarditis, anæmia, leukæmia, exophthalmic goitre, osteomyelitis, diabetes, appendicitis, peritonitis, carcinoma of stomach, intestines, gall bladder, lung, breast, uterus, kidney, etc.

In one case in which the diagnosis, though at first doubtful, was later considered to be biliary calculi, we obtained a positive reaction. The history of the case is as follows:

[1] Thayer: Johns Hopkins Hospital Bulletin, vol. viii., No. 72, p. 55.

Bertha D——, thirty-five, housewife, married, admitted to Mt. Sinai Hospital, January 20, 1897. Previous history negative; never had typhoid fever: had rheumatism six months ago. Present history, of three months standing, began with headache, loss of appetite, vomiting, and cramps in the abdomen. The vomiting persisted off and on for two months, while the headache and the pain in the abdomen came on in attacks. Bowels are always constipated. Never was jaundiced. No pulmonary, cardiac, or urinary symptoms. Has lost thirty-five pounds in weight, and since three weeks has felt very weak and been confined to bed. Was seen by several physicians, who suspected malignant disease of the stomach. Now complains of paroxysmal general abdominal pain and weakness. On her admission to the hospital, her general condition was poor; she was emaciated and anæmic. Physical examination of lungs and heart was negative. Her spleen was not enlarged. The liver dulness extended from the fifth rib to two and one-half fingerbreadths below the free border of the ribs. She had considerable tenderness in the right hypochondriac region. During the seven weeks the patient remained in the hospital, she had a number of attacks of pain in the right hypochondriac region with chills and fever up to 102°–103° F. during the attacks. Examination of the gastric contents revealed nothing abnormal. There was no Ehrlich diazo reaction. One week after her admission her spleen was aspirated for diagnosis and cultures were made from the blood obtained. No typhoid bacilli were found. The diagnosis of biliary calculi seemed finally certain, but the patient refused operation, and left the hospital. A number of examinations were made of this patient's blood by all the methods, and every time a positive reaction was obtained. At one time it was thought possible that she might have had a mild attack of typhoid fever in the three weeks preceding her admission to the hospital. A careful study of her symptoms has convinced us that this case must be put down as positively not a case of typhoid. Whether the patient, who was very ignorant and stupid, had had the disease during the the months previous we do not know.

A study of the results I have obtained has led me to come to the following conclusions:

The reaction can in no sense be considered an absolute diagnostic method early in the disease. In only eight per cent. of the cases was the reaction present in the first week of the disease, and in fourteen per cent. its appearance was delayed until after the second week of the disease, by which time a clinical diagnosis had already been arrived at. The test is of undoubted value in irregular and doubtful cases. Thus, in our series we had two cases of the disease, occurring in patients of about sixty and seventy years of age, in which many of the symptoms pointed toward pneumonia and in which the presence of the Widal reaction made the attending physician suspect typhoid fever. Both patients died, and in both cases the post-mortem examination showed the presence of the characteristic typhoid lesions. In another case the patient was sent to the hospital and operated on for appendicitis, a large abscess being evacuated: a reaction was found and the disease ran a typical typhoid course. In hospital practice, in which cases are often seen for the first time as late as the second week of the disease, the test is also of value. If the reaction is present, we may be fairly certain that the disease is typhoid fever. The absence of the reaction does not prove that the patient is not suffering from that disease.

In the second place, we must recognize in the test a valuable aid for the differentiation and rapid recognition of the typhoid bacillus, especially from the colon bacillus, the "psittacose" bacillus, and other kindred organisms.

In the third place, the Widal reaction affords us additional proof that the Eberth bacillus is the specific cause of typhoid fever.

We are justified in hoping that the idea involved in the Widal reaction may be proven to be applicable to the study of other diseases. It might thus be possible that during an epidemic of cholera, one could by means of a "cholera reaction" differentiate true cases of cholera from the cases of "cholerine" which so frequently accompany epidemics of that disease. After this paper had been written, an article appeared in *The Lancet*, by two English observers,[1] in which they describe how they have successfully applied the methods of serum diagnosis to the diagnosis of Malta or Mediterranean fever, and demonstrated that the serum of patients who had this disease had the sedimenting action on bouillon cultures of the specific organism.

This and other questions offer a wide and promising field for further research, and we must look to the future for the solution of the many interesting problems which a study of the principles of the serum diagnosis of disease has laid before us.

A REPORT OF THREE CASES OF THE CRETINOID CONDITION IN THE SAME FAMILY, TREATED WITH THYROID EXTRACT.

By C. S. CAVERLY, M.D.

RUTLAND, VT.

Thyroid therapy has lent additional interest to cases of cretinism and myxœdema, always interesting from their rarity. The three cases here reported seem noteworthy, because the patients are brothers and sister. The two older are marked cretins, Eddie, the younger of the two, being quite a typical case, while the baby has the cretinoid tendency well marked, and would undoubtedly in time become as decidedly cretinoid as the older children. These cases came under my observation during the latter part of April last. This was the family history elicited:

Mrs. R—— (the mother) is thirty-five years old; born near Dublin, Ireland; reared in Scotland. Her father and mother are both dead, the former by an accident, the latter of "kidney trouble." Five brothers died in infancy, the cause of their deaths being unknown. One brother living has been an inmate of an insane asylum. She is a large fleshy woman, somewhat inferior intellectually, and gives no history of any injury or unusual illness during her pregnancies, or at other times. Her labors have always been normal.

Mr. R—— (the father), thirty-five years old, was also born near Dublin, Ireland. His father and mother are both living and healthy. One healthy brother is living. He is a temperate, hardy-appearing man, and is so reported by his employer, for whom he has worked as gardener for seven years.

These parents know of no case of cretinism or of goitre in their native place in Ireland. They have lived in Vermont about fifteen years. Their family consists of these children, all apparently healthy and normal at birth; Thomas, eleven years, a normal boy; James, nine years eleven months, a cretin; Eddie, eight years three months, a cretin; Michael, seven years, a normal boy; Willie, five years, a normal boy; Elizabeth, one year four months, cretinoid.

The history and present condition of the cretins, as noted at this time, was as follows:

James was apparently a healthy baby for the first six months. After this he did not grow and develop like other children. His first teeth, which he still retains, appeared at three years. He has never talked.

Fig. 1.—James (nine years eleven months).

Fig. 2.—Eddie (eight years three months).

Fig. 3.—Elizabeth (sixteen months).

[1] Wright and Smith: Lancet, 1897, vol. i., No. 10.

He can stand by taking hold of pieces of furniture, but cannot walk. He has a large head, flattened on top; coarse red hair, very thin: coarse features, with thick lips and heavy eyelids, and he usually protrudes his tongue. His disposition is not unamiable. He makes a grunting sound when disturbed, but has when at rest a more agreeable, or, more correctly, a less repulsive facial expression than his next younger brother. His arms and legs are heavily built and rather crooked. The belly is full, and the navel protrudes. Height, thirty-two and one-half inches: pulse, 84; temperature (axillary), 96.5° F. Lips blue and skin cold, mottling on exposure. The skin is dry and rough to the touch. There is no appreciable swelling over the clavicles, nor can the thyroid gland be felt. He is clumsy and awkward in all his movements.

Eddie: The above description applies to this child as well, except that all the cretincid characteristics are emphasized in his case. He has a more repulsive face, constantly protrudes his tongue, and his disposition is more ugly. He resents any disturbance, and gives utterance to loud animal cries. He cannot walk or even stand, has his baby teeth, and shows an utter lack of intelligence. He is thirty-one and one-half inches tall, and has an axillary temperature of 98° F.

Elizabeth grew normally up to the end of the first year. Since January she has been getting more and more like the two boys. She is evidently tending in the same direction, mentally and physically. She has no teeth, no use of her legs, the same coarse features, thin red hair, protuberant belly, heavy limbs, and mental stupidity, though in less degree, as the two boys. She measures twenty-six and one-fourth inches. The photographs of these children, taken before they were put upon the thyroid treatment, are here reproduced. One group shows all three together, and the other the two older beside a normal brother, five years old.

Fig. 4.—James and Eddie beside a normal brother of five years.

The children were at once put upon the thyroid treatment. At first they were given the dry powder of Parke, Davis & Co. The initial dose was one grain daily, and this was regularly increased to ten grains daily in the cases of the boys, and to five grains daily in the case of the baby.

Eddie, whose cretinoid condition was most marked, bore the treatment best. It produced some excitement in all at first, and their faces would become flushed after taking it. James had wakeful nights, derangement of the stomach, swollen glands in the neck during the early part of the treatment, though it was doubtful whether these symptoms all depended upon the thyroid. The boys' mouths were sore, but the decaying milk teeth seemed at least partially responsible for this. After two months the thyroid preparation was changed to five-grain tablets of Fairchild Bros. & Foster. The baby cut her first teeth in August. She had a severe attack of gastro-intestinal disturbance also during this month, beginning with a series of convulsions. She was taking five grains of the thyroid daily at this time, which was decreased for a time but gradually restored to that dose as she got better. She walked in September.

The first and most noticeable effect of the treatment in all these cases was an improvement in the circulation, their temperature becoming quite normal, and their extremities warm and the skin of a more natural color. The next effect noticed was a steady loss of flesh, which was very noticeable, though I never succeeded in getting them weighed. They soon began to use their limbs, and the boys walked within two months. Their minds did not keep pace with their bodies, but they learned such words as "mamma," "horse," "chair," etc. It was evident, too, that they attached correct meanings to these words. The baby became more diffident, and acted more like a normal child of a year and a half. The boys made good use of their legs in running away and otherwise taxing the patience of the parents.

Their present condition (March 20, 1897) is a marked improvement over that of ten months ago, in every respect. James measures 39 inches, a gain of $6\frac{1}{2}$ inches; Eddie, $37\frac{1}{4}$ inches, a gain of $5\frac{3}{4}$: and the baby, $31\frac{1}{4}$ inches, a gain of 5. Their tongues no longer protrude, their bellies are smaller, and the navel of neither projects scarcely any. The boys are shedding their baby teeth, and Eddie has several permanent ones. The boys talk somewhat, James rather less than Eddie. The latter connects words into intelligible sentences, and in mental growth is outstripping the older. He has acquired more common knowledge, feeds himself, and knows enough to go to the closet when he urinates or his bowels move. James does not yet show so much intelligence in these respects. Eddie's disposition has kept pace with his mental improvement, and he is now quite amiable. The baby's present condition is quite that of a normal child. She talks, walks, and has eight teeth. It is not unlikely, however, that she would lapse into the former condition if treatment were now suspended, though it seems probable that a long use of the thyroid in her case may result in a permanent cure. The cases of the two older are of course less promising as to final results. At this time it can only be said that they have shown improvement in most ways, and it is hoped the enthusiasm of the parents at the results so far apparent may continue until it can be determined just how much this plan of treatment can do for them. Each of the boys now takes twelve and one-half grains of the thyroid daily, and the girl seven and one-half.

It is not my purpose to venture an explanation of these cases of cretinism. I certainly have none. The older literature of the disease usually speaks of its

being peculiar to or endemic in certain European countries and in certain parts of this country. Mountainous limestone regions are said to favor it. This of course is descriptive of Vermont, and I find this State mentioned by one author[1] as one of those in this country in which the disease is met with. Yet I have never seen a case here before, nor can I learn of one. Dr. Frederick Peterson tells me that he has found none reported from Vermont.

Cases of cretinism, however, are being reported with increasing frequency in recent pædiatric literature, in this country. Yet these reports do not come from any one locality especially. They are from Massachusetts,[2] Pennsylvania,[3] Ohio,[4] New York,[5] Maryland,[6] etc. Dr. G. W. Crary[7] says sporadic cretinism is not rare; it occurs in all parts of the United States. The latter part of his statement, at least, would seem to be correct. I feel quite sure that it is not endemic in this State.

The cases here reported, occurring as they do in one family, point quite strongly to some hereditary taint. I have been suspicious that this came from the mother's side. I can offer no facts, however, to substantiate this suspicion, further than those brought out in her history. While, then, isolated or sporadic cretinism does not seem to be very rare in this country, the combination of three cases in a single family is, so far as I can learn, unique.

I wish to acknowledge in this connection my indebtedness to Drs. M. Allen Starr and Frederick Peterson, of New York, for valuable advice in the management of these cases, and to my associate, Dr. S. W. Hammond, of this city, for assistance in carrying out the details of the treatment.

QUEER EYES IN QUEER PLACES.

By JAMES WEIR, Jr., M.D.,

OWENSBORO, KY.

Sight is the result of the conversion of one form of motion into another—a conservation, as it were, of energy. Thus, waves of light coming from a luminous body are arrested by the pigment cells of the retina in our eyes, and are transmuted into another form of motion, which is called nerve energy (in this instance, sight). It would seem that as far as sight (vision is not included) is concerned, eyes of very simple construction would amply satisfy the needs of thousands of creatures whose existence does not depend upon vision. This supposition is undoubtedly correct; there are many creatures in existence to-day with eyes so exceedingly simple that they can form no visual picture of objects—they are only able to discriminate between light and darkness. Primitive eyes appear in animals very low in the scale of life: probably the most remarkable of these early organs of sight are to be found in the medusa, or jellyfish (Fig. 1). This creature, with its bell-shaped body and pendent stem, bears a striking resemblance to an umbrella; noting this resemblance, naturalists have given the name *manubrium*, "handle," to the stem. Around the edge of the umbrella and situated at regular intervals are certain round cell-like organs, which vary considerably in number. Some species have only eight, while others have sixty, eighty, and even (in Æquorea) as high as six hundred. These so-called "marginal bodies" are the eyes of the jellyfish. By many biologists these organs are considered to be ears; they contain within their capsules transparent bodies, which some scientists deem otoliths or "hearing-stones." Experimentation and microscopical examinations, however, have taught me very recently to believe otherwise. In these marginal bodies there is always a deposit of pigment; this is unquestionably a primitive retina, while the transparent disc is indubitably a primitive lens. That these creatures can tell the difference between light and darkness is a fact easily demonstrated. Time and again have I made them follow a bright light around the walls of the aquarium in which they were confined. On one occasion I made some medusæ tipsy, and their drunken gravity as they rolled and staggered through the water in pursuit of the light was as sorrowful as it was instructive; their actions in this respect were those of intoxicated men. After I had siphoned off the alcoholized water and replaced it with pure water, they rapidly regained their normal status; whether or not any of them felt any evil effects from their involuntary debauch, I am not prepared to state.

Fig. 1. Jellyfish (*Eretima gigas*), Showing Marginal Eyes.

The eyes of sea urchins are rather highly developed, having corneæ, retinæ, and lenses. The lens generally lies in a mass of pigment, and, as Lubbock remarks, looks like a brilliant egg in a scarlet nest. The eyes are scattered over the dorsal surface of the creature's body, and are commonly situated just beneath the skin; they are, however, sometimes elevated on pear-shaped bulbs. The eyes of starfish are generally quite simple in character, as far as I have been able to determine, being pigmented spots which are supplied with nerves. In several species, however, I have been able to make out lenses; it may be that all starfish eyes have lenses, only they have not yet been discovered. The eyes are arranged along the rays or arms, and vary in number.

Even the stay-at-home and humble oyster has eyes (not the round, fleshy muscle called the "eye" by gourmands and epicures, but bright spots around the edge of the mantle)—primitive eyes, it is true, yet amply sufficient for the needs of a domestic, non-travelling, home body like the oyster.

In most of the worms the eyes are simple ocelli, spots of pigment supplied with nerves. These eyes can discriminate between light and darkness, which is all that is required of them: but in the Alciope, a small sea-worm, these organs are brought to a high degree of perfection. This worm is exceedingly transparent, so that when observing it, it is difficult to make out more than its large orange eyes and the violet segmental organs of each ring. It looks like an animated string of violet discs surmounted by a pair of orange-colored eyeglasses. The eye of this creature is strikingly like that of a human being; it has a cornea, an

"eye-skin" (anterior chamber, Fig. 2), a lens, vitreous humor (posterior chamber), and retina.

Another aquatic worm, Myrianida, is still more remarkable, not only on account of its eyes, but also on account of the wonderful way in which it reproduces its young. When seen swimming in the water it presents the appearance of a long, many-ringed worm, which impels itself through and by the aid of its hundreds of flat oar-like legs. Closer inspection reveals the startling fact that this seemingly single worm is really a multiple worm—six or more individuals being joined together, thus forming a living chain. This creature reproduces itself by fissigemmation; that is, when the young worms arrive at a certain age they separate from the parent worm and begin life as individuals. These in turn eventually become multiple worms and divide into individuals, and so *ad infinitum*. The tail worm, or that section farthest from the head, is the oldest and is always the first to leave its comrades and take up a separate existence. The adverb always in the above sentence is, strictly speaking, not exactly accurate, for on one occasion I saw the separation occur at the second head from the tail, thus producing twins. The two sections came apart, however, in a very few seconds after their departure from the colony. I am inclined to believe that this deviation from the normal was due to accident; probably to manipulation. This annelid is really "many in one" until the very moment of division; the alimentary canal, nerves, blood-vessels, etc., extend in unbroken continuity from the head of the parent worm to the tail of the last section. In every fourth (sometimes fifth) ring two round, dark-colored spots will be observed; these spots are ocelli, and some of them eventually become the eyes of young worms. These organs even in their embryonic state possess sight, for they have special nerves and pigment cells; they can differentiate between light and darkness.

Fig. 2.—Alciope.

The snail carries its eyes in telescopic watchtowers. This animal is, for the most part, nocturnal in its habits, and, since prominent and commanding view points are assigned to its organs of vision, one would naturally expect to find a comparatively high degree of development in them; and this supposition is correct. The eyes of this creature are in the extreme tips of its "horns," and consist of (1) a cornea, (2) a lens, and (3) a retina (Fig. 3). Lubbock is rather disposed to decry the visual powers of the snail; my conclusions, drawn from personal observations, are, however, directly the opposite. The position of the eyes at the extreme tips of the "feelers" naturally indicates that they subserve a very useful purpose; otherwise they would not have attained such prominence and such a high degree of development. Actual experimentation declares that the garden snail can see a moving white object, such as a ball of cotton or twine, at a distance of two feet. In my experiments I used a pole, ten feet in length, from the tip of which a white or dark ball was suspended by a string. The ball was made to describe a pendulum-like movement to and fro in front of the snail on a level with the tips of its horns. Time and again I have seen a snail draw in its horns when it perceived the white ball, to it an unknown and terror-inspiring object. I have likewise seen it change its line of march and proceed in another direction, in order to avoid the mysterious white stranger dancing athwart its pathway. Dark-colored spots are not so readily perceived: at least, snails do not give any evidence of having seen them until they are brought within a foot of the creatures under observation. A snail will generally see a black ball at twelve or fourteen inches: sometimes it will not perceive the ball, however, until it has been brought to within six or eight inches of its eyestalks. During the season of courtship snails easily perceive one another at the distance of eighteen or twenty inches. I have often watched them at such times, and have been highly entertained by their actions. The emotional natures of snails, as far as love and affection are concerned, seem to be highly developed, and they show plainly by their actions when courting the tenderness they feel for one another. This has been noticed by many observers of high authority, notably Darwin, Romanes, and Wolff. Montegazza, a distinguished Italian scientist, in his "Physiognomy and Expression," writes as follows: "As long as I live I shall never see anything equal to the loving tenderness of two snails, who, having in turn launched their little stone darts (as in prehistoric times), caress and embrace each other with a grace that might arouse the envy of the most refined epicurean." Darwin tells us that two snails, one of them an invalid, the other in perfect health, lived in the garden of one of his friends. Becoming dissatisfied with their surroundings, the healthy one went in search of another home. When it had found it, it returned and assisted its sick comrade to go thither, evincing toward it, throughout the entire journey, the utmost tenderness and solicitude. The healthy snail must have used its sight as well as its other senses to some purpose, for, if my memory serves me correctly, we are told that the sick snail rapidly regained its health amid its new surroundings.

The crayfish also has its eyes at the tips of eyestalks, but the eyes of this creature are very different indeed from the eyes of the snail. They are what are known as compound eyes, a type common to the crayfish and lobster families, and also to a large number of insect families. Viewed from above, the cornea of a crayfish's eye is seen to be divided into a number of compartments or cells, and looks in this respect very much like a section of honeycomb. The microscope shows that in each one of these cell-like compartments there is a transparent cone-shaped body; this is called the crystalline cone. The apex of this cone is prolonged into an exceedingly small tube, that enters a striped spindle-like body called the striated spindle: the entire structure is called a visual rod. Nerve fibrils emanating from the optic nerve enter the striated spindle at its lower extremity,

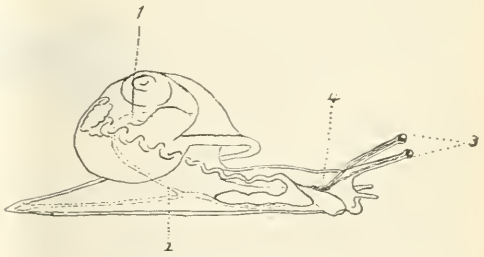

Fig. 3.—Eyes of Snail (Helix albolabris). 1, Heart; 2, aorta; 3, eyes; 4, superior head ganglion (brain and optic nerves).

and in this way nervously energize the visual rod. There is a deposit of pigment about the visual rod which arrests all rays of light save those which strike the cornea parallel to the long axis of the crystalline cone. We see from this that the visual picture formed by a crayfish's eye must be made up of many parts; it is, in fact, a mosaic of hundreds of little pictured sec-

tions, which, when united, form the picture as a whole. Each visual rod receives its impression from the ray or rays of light reflected from the object viewed that strike it in the line of its long axis; the other rays are stopped by the layer of pigment cells. When the impressions of all the visual rods are added together, the sum will be a mosaic of the object, but such a perfect one that the junctions of its many portions will be absolutely imperceptible.

The crayfish can see quite well. It has been thought that this creature used its sense of smell more than its sense of sight in the procurement of its food. This is undoubtedly true when the animal is surrounded by water that is muddy or that is otherwise rendered opaque. The odoriferous particles coming from the food being carried to the creature by the water, it follows them until it arrives at their source. It is different, however, in clear water or on land. I have seen crayfish rush down stream after bits of meat thrown to them, thus showing that here, at least, the sense of sight directed them. Again, I have enticed crayfish from clear streams by slowly dragging a baited hook in front of them. Moreover, when high and dry on land, I have seen them follow with their eyes and bodies the tempting morsel as it was waved to and fro in the air above their heads.

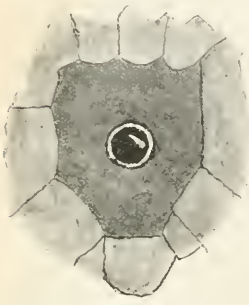

Fig. 4.—The Third Eye of a Small Lizard (Calotis).

The female crayfish carries her eggs beneath her tail, and, when they have hatched out, the young find this sheltering member a safe and cosy dwelling-place until they have grown strong and fully able to enter life's struggle. At such times the mother crayfish is quite brave, and will do battle with any foe. With her eyestalks protruded to their utmost extent, she vigilantly watches her enemy. Her eyes follow his movements, and her sharp nipper is held in readiness for immediate use. Actual experimentation has taught me that crayfish can descry a man at the distance of twenty or twenty-five feet. When approaching a crayfish "town" for the purpose of making observations, I use the utmost caution; otherwise, each inhabitant will retreat into its burrow before I can come close enough to observe them even with my fieldglass.

Another queer-eyed individual whose dwelling-place during the greater portion of its life is in ponds or small streams, is the whirligig beetle, or Gyrinus. This insect is a true cosmopolite, however, and is as much at home on dry land as it is in the water. All seasons seem to be alike to it, for during the hottest days of summer and the coldest days of winter (that is, if there is sunlight and no ice) it may be seen on the surfaces of ponds and small streams, gyrating hither and thither in a seemingly mad and purposeless manner. Several of them will be seen at one moment floating on the water, still and motionless; the next moment they will be observed darting here and there over the surface of the water, their black and burnished backs shining in the sunlight like brilliant gems. Suddenly it is "heels up and heads down," and they disappear beneath the surface, each of them carrying a bubble of air caught beneath the wing-tips; or, as Mr. Gibson expresses it, "they carry a brilliant lantern that goes gleaming like a silver streak down into the depths, for a bubble of air is caught beneath their black wing covers, and a diamond of pure sunlight accompanies their course down among the weeds until they once more ascend to the surface."

This little beetle is well-provided with eyes, for it has a large pair beneath its head, with which it sees all that is going on in the water, and another pair with which it keeps a bright lookout above. That it has remarkably keen vision with the latter pair, any one that has tried to steal upon them unawares can testify.

The queerest of all queer-eyed animals is probably the Periophthalmus, a fish inhabiting the coasts of China, Japan, India, the Malayan Archipelago, and Eastern Africa. I use the word coasts advisedly, for this strange creature, when in pursuit of its prey, leaves the sea and comes out on the sands, thus existing for the greater portion of its life in an element which, according to the nature of things, ought to be fatal to it. The laws of evolution have, however, eminently prepared it for its peculiar mode of life, for its gill cavities are so large that when it abandons the sea it carries in them a quantity of water which yields up the necessary supply of oxygen. Its locomotion has been provided for likewise, for continued use along certain lines has so developed its pectoral fins that the creature uses them as legs, and jumps along at a surprising rate of speed. Its eyes are very large and prominent, and possess, for a fish, the peculiar faculty of looking around on all sides; hence its name, Periophthalmus, which is derived from the Greek words *περί*, around, and *ὀφθαλμός*, eye. These eyes are situated on top of the animal's head, and present a very grotesque appearance.

The favorite food of this fish is a naked mollusk called Onchidium. And, in the matter of eyes, this last-mentioned creature is itself worthy of remark. Its cephalic or head eyes are like those of other mollusks, and not worthy of special mention; but its dorsal eyes, sometimes several hundred in number, are truly remarkable. These dorsal eyes, although they are very simple in structure, in type are the same as those of vertebrate animals, having corneæ, lenses, retinæ, and "blind spots." (In the vertebrate eye the spot

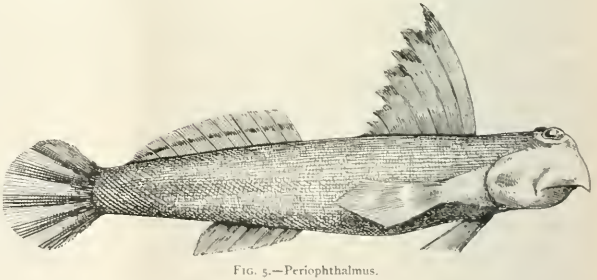

Fig. 5.—Periophthalmus.

where the optic nerve pierces the external layer of the retina is sightless; hence it is called the "blind spot"). When this mollusk sees the Periophthalmus bounding over the sands (and that it does see it is beyond question), what does it do? It contracts a thousand or so of little bladder-like cells in the skin of its back, thereby discharging a hail storm of minute concretions in the face of its enemy! The fish, terrified and amazed by the volley, turns aside, and the mollusk is saved. Thus we see that its dorsal eyes are of great advantage to Onchidium. It is not able, like Periophthalmus, to move these eyes, yet, situated as they are all over its back, it possesses the power of seeing in every direction.

The Greeks were, unwittingly, very near an anatomical truth when they ascribed to certain monsters, called cyclopes, only one eye apiece, which was placed in the centre of their foreheads. The cyclopean eye exists to-day in the brains of men in a rudimentary form, for in the pineal gland we find the last vestiges of that which was once a third eye, and which looked out into the world, if not from the centre of the forehead, at least from very near that point. There is alive to-day a little creature which would put to shame the one-eyed arrogance and pride of Polyphemus, and Arges, and Brontes, and Steropes, and all the rest of the single-eyed gentry who, in the days of myths and myth makers, inhabited the "fair Sicilian Isle." The animal in question is a small lizard, called Calotis. (Fig. 4). Its well-developed third eye is situated in the top of its head, and can be easily seen through the modified and transparent scale which serves it as a cornea. Many other lacertilians have this third eye, though it is not so highly organized as it is in the species just mentioned. A tree lizard, which is to be found in the mountains of East Tennessee and Kentucky, has its third eye quite well developed. This little animal is called the "singing scorpion" by the mountaineers (by the way, all lizards are scorpions to these people), and is a most interesting creature. I heard its plaintive "peep, peep, peep," on Chilhowee Mountain a number of times before I became aware of the fact that a lizard was the singer. On dissection, the third eye will be found lying immediately beneath the skin; it has a lens, retina, and optic nerve.

THE TREATMENT OF CONTUSIONS OF THE LIDS ("BLACK EYE").[1]

By CHARLES H. MAY, M.D.,

CHIEF OF CLINIC AND INSTRUCTOR IN OPHTHALMOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY, NEW YORK; PROFESSOR OF DISEASES OF THE EYE AND EAR, COLLEGE OF PHYSICIANS AND SURGEONS, BOSTON, ETC.

In the great majority of instances contusions of the lids lead to nothing worse than swelling and discoloration: the chief interest which is attached to the subject, therefore, is connected with the removal of the inconvenient and embarrassing disfigurement, or the hastening of nature's process of absorption of the escaped blood.

On account of the cellular nature of the tissue of the lids and surrounding parts, the swelling and discoloration are apt to be great and out of all proportion to the amount of force encountered in the accident. These tissues are firmly adherent to the supraorbital margin; hence the swollen and discolored area is usually limited by this line. Sometimes we find, after bruises or operations, that the discoloration involves the inner portion of the lids of the side not affected, creating the impression that the fellow eye has been involved to a lesser extent. This peculiarity is due to the fact that the blood has been poured into the cellular tissue surrounding one eye, and has travelled across the nose and found lodgement on the opposite side, the thickness of the skin over the bridge of the nose obscuring the route.

In most cases contusions of the lids are produced by blows; less frequently they result from other forms of violence: sometimes they occur after operations upon the eyeball or its adnexa.

It is a remarkable fact that contusions of the lids are rarely accompanied by serious injury to the eyeball, showing how well the organ of vision is protected by the bony margins of the orbit and the lids.

In an uncomplicated case, the course is somewhat as follows: Within an hour or two after the infliction of the violence there will be considerable swelling, redness, tenderness, and more or less pain: then discoloration shows itself. The swelling is apt to subside in two or three days, but the discoloration remains, presenting successive hues—dark red, brown, or black, becoming fainter, then greenish or bluish, and finally yellow. In ten days or two weeks all signs of the bruise will have disappeared.

The complications which may occur are: hemorrhage affecting some part of the eyeball (1, subconjunctival; 2, into the aqueous chamber; 3, into the vitreous; and 4, retinal); separation of the attachment of the iris; paralysis of the iris and ciliary muscle; dislocation of the lens; rupture of the globe; rupture of the choroid; fracture of some of the bones forming the walls of the orbit, the orbital arch, or the optic foramen; emphysema; and abscess of the lids.

The discussion of possible complications does not lie within the scope of this paper. They are mentioned so as to show the necessity of examining the eyeball and orbit in every case of "black eye," for, though rare, such complications are observed.

It is not an easy matter to examine the eyeball in a patient in whom the lids are closed as a result of swelling, and it becomes still more difficult when considerable tenderness is added. To obtain a view of the eyeball is, however, essential. Some patients will assert that they have become blind on the contused side, and will not become convinced of the escape of the eyeball from injury until the swollen lids are separated forcibly and their ability to see is thus proven to them.

In separating such lids and swollen lids of any description, or those forcibly closed by spasm, separation will be the more effective the nearer the margins of the lids the fingers be applied. To apply the examiner's fingers at some distance from the edges of the lids accomplishes nothing, except, perhaps, eversion. If we wish to separate the lids so as to get a view of the cornea and sclera, we must apply the finger tips at or close to the margin of the lids, roll the latter in somewhat, and accompany separation by a certain amount of pressure toward the eyeball. An expert oculist can do this with two fingers of one hand; but for one who is less experienced it is better to use the index fingers or the middle fingers of both hands—one above and the other below. In the process of separation or during inspection he must be careful that the finger does not slip upon the cornea and cause an abrasion—a result which is more likely to happen if the nails of the examiner's fingers have not been trimmed sufficiently close.

The treatment of contusions of the lids depends upon whether we see the patient early, when there is considerable swelling, or not until later, when the discoloration is the prominent feature. If he is seen early, treatment consists of cold compresses or cooling or evaporating lotions: with these we can diminish the amount of swelling and discoloration, though it is impossible to prevent them entirely. If the patient is seen later, hot compresses and massage are indicated, to hasten the disappearance of the discoloration.

Cold compresses are to be applied continuously at first, but not by means of an ice bag or a piece of ice wrapped in a handkerchief and applied directly to the swollen lids, since these furnish too intense and too constant cold. Small compresses of lint, lintine, or flannel, fourfold or sixfold, measuring one and one-half inches in diameter, are to be cooled upon a block of ice and then transferred to the lids. Several compresses of this sort are placed upon the ice, and an exchange between the warm one on the lids and a cool one from the ice is effected every minute or two. In this connection, it may be well to mention that care should be taken not to allow the cold compress to cover

[1] Read at the April, 1896, meeting of the Metropolitan Medical Society.

the nose, since such carelessness causes an acute coryza in many persons. Cold compresses of this sort are to be applied during the first twenty-four hours, either continously or every second or third hour for an hour at a time, depending upon the amount of redness and swelling. The sensations of the patient usually guide us in determining the proper amount of cold; when the compresses are used too continuously, they will become uncomfortable.

The application of cooling and evaporating lotions are of service, though less potent than iced compresses. Such cooling lotions consist of:

℞ Acidi borici ..... ℥ ij.
Spir. vini ..... ℥ ij.
Aquæ ..... q.s. ad Oi.

Or:

℞ Tinct. arnicæ ..... ℥ ij.
Aquæ ..... q.s. ad Oi.

Both of these are to be applied cold, the compresses being wrung out of the boric acid or the arnica mixture and changed frequently.

After twenty-four to forty-eight hours, when the swelling has subsided, the discoloration will show itself in a more pronounced manner; the lengthy duration of this stage can be cut short by hot applications and by massage. Flannel cloths are to be wrung out of hot water—as hot as can be borne—and allowed to lie upon the lids, being changed every minute or two: such applications are continued for an hour at a time and applied three times a day, or oftener, if it is especially desirable to hasten the return of the lids to a normal condition. When the skin is very sensitive, especially in women, it is well to apply a little white vaseline or any variety of bland salve to the eyelids previous to the use of the hot compresses, so as to prevent soreness and irritation of the skin.

Massage is a very satisfactory means of causing a rapid disappearance of the discoloration. The area involved is smeared with the ointment of the yellow oxide of mercury, or white vaseline will answer equally well, and then gentle massage is practised for five or ten minutes at a time, or longer, several times a day.

If it is extremely desirable to cause a very rapid disappearance of the blood stain, the hot compresses may be used continuously and the massage for a number of hours. By these means the disfigurement may be almost if not entirely removed within twenty-four hours, or even sooner, after the subsidence of the swelling.

The treatment just described, though simple, is very laborious, and but few patients are willing to devote the necessary time to it, since, after all, the condition is one which is important only on account of the disfigurement. In such cases we may send the patient to one of the "black-eye artists" to be found in every city, who paint the lids and thus cover up the ecchymosis.

It is the practice among the laity, and especially with pugilists, to prick or incise the swollen lids as soon as possible, and to suck out or press out the blood, or to apply leeches to the bruised area. This has a favorable effect in reducing the amount of swelling and subsequent discoloration, but it is objectionable because it produces an open wound, which may become infected and may lead to abscess of the lid.

Some of the men who make a business of painting "black eyes" also treat them so as to remove the discoloration, and claim to do this in from four to seven hours. The writer visited the rooms of one of these men and watched his process of treating a "black eye." The procedure is not attempted until the swelling has subsided. The patient lies upon a lounge, and for several hours a poultice is applied to the discolored lids. This poultice consists of scrapings from some fresh, thick, fleshy root, the nature of which is kept secret. Probably it is the root of the black bryony, mentioned by Lawson: "A remedy which has for many years received considerable credit is a poultice of the black bryony root. It is made by mixing some of the black bryony root scraped finely with a little crumb of bread. This is placed in a muslin bag over the palpebræ for several hours together, and usually it has an excellent effect in promoting the action of the absorbent vessels." The writer satisfied himself that such a poultice is really effective in dispersing and removing the discoloration.

But if massage were used for a number of hours, it would probably also cause a disappearance of the disfigurement. Of course, no oculist cares to devote so much time to such a trivial affection or condition: hence all such procedures fall to the lot of men who make a business of painting over "black eyes" and of removing the disfigurement in various ways, usually by means of the fresh-root poultice referred to.

Though it is not intended to discuss the complications which occasionally occur with contusions of the lids, a brief reference to the treatment of two of them may be in place. When the wall of the orbit has been fractured in any place which permits communication with neighboring cells, emphysema is apt to occur. This is diagnosticated by the occurrence of crepitation upon palpation. It is made worse when the patient blows the nose, sneezes, coughs, or strains in any way. When this complication exists, it is well to caution the patient against such efforts, and in the way of treatment to apply a firm bandage. Abscess of the lids is more apt to occur in patients whose general condition of health is poor, especially if there is an abrasion of the skin in addition to the contusion. Such abscesses are to be opened by a horizontal incision.

692 Madison Avenue, New York City.

Capital Operations without Anæsthesia.—In a paper read by Dr. J. J. Buchanan, surgeon to the Pennsylvania Railway Company, at the meeting of the National Association of Railway Surgeons, in St. Louis, the following conclusions are presented: (1) Patients with limbs so crushed as to require amputation, who are in good general condition, should be operated on at once. (2) Those who present evidences of severe shock and great loss of blood should be treated by external heat and stimulants, including the hypodermic use of whiskey, digitalin, strychnine, and nitroglycerin, and the rectal injection of whiskey, strong coffee, and hot water. The crushed limb should be disinfected as completely as possible, and six per thousand saline solution of not less than two quarts for an adult be allowed to flow into a vein, this infusion to be repeated, if necessary, at intervals of a few hours, according to the effect produced. (3) If by these efforts complete reaction should be established, anæsthesia and amputation should be proceeded with as in ordinary cases. (4) If, however, a moderate or doubtful reaction only should occur, the propriety of a rapid amputation without anæsthesia should be seriously considered, if the consent of the patient be gained. (5) The complete disinfection of crushed, lacerated, dirty and infected limbs usually cannot be accomplished. (6) The sooner such limbs are removed, the better, provided the patient's life be not lost in the operation. (7) If, notwithstanding the vigorous treatment just mentioned, an amputation, either with or without anæsthesia, be fraught with great risk, it is far better to disinfect as thoroughly as possible, drain well, pack all open spaces, and take the chance of infection, which, in most doubtful cases, is probably less than the risk of death from shock following operation.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, April 10, 1897.

THE POSSIBILITY OF RECOVERY FROM TUBERCULOUS MENINGITIS.

THERE are few diseases of childhood that are regarded as more surely fatal than tuberculous meningitis, and in cases of reported recovery the tendency is rather to question the correctness of the diagnosis than to accept the fact of a cure. But there are a few instances in which lesions have been found post mortem which pointed indubitably to a previous attack of meningitis, from which the history of the case showed that there had been apparently a perfect recovery.

One such case, a most convincing one, reported by Janssen about a year ago, is quoted by Collins in the article on meningitis in the latest volume of the "Twentieth Century Practice." In this case the patient presented typical symptoms of meningeal tuberculosis, but recovered under the administration of nine hundred grains a day of iodide of potassium. Three years later the patient died from pulmonary tuberculosis, and at the autopsy evidences were found in the meninges of previous tuberculous disease.

More recently, W. Hale White reports a similar case in *Brain*, winter number, 1896. The patient was a boy, thirteen months old, who was admitted to the hospital with a history of having had frequent attacks of convulsions during the previous two weeks, these having succeeded a prodromal period of vomiting after eating and fretfulness of a week's duration. The child lived only four days after admission to the hospital, presenting marked symptoms of meningitis. At the autopsy there was much recent basal meningitis. In each fissure of Sylvius about half an inch from its commencement was a caseous tuberculous nodule, the size of a very large pea. Both these nodules were in the meninges, and could be easily freed from the brain. No other tuberculous deposit was found anywhere. Even if we are prepared to admit that meningitis is, in certain rare cases, capable of recovery, yet, as we have remarked, when the patient gets well there is always a certain element of doubt in the case. We think, therefore, with the author, that this case is worthy of record, "for the presence of two old caseous tuberculous nodules in the meninges, as well as recent acute inflammation of them, showed that there must have been some meningitis previous to that which killed the child, unless we believe that they represented an earlier stage of the same attack as that which was fatal, but the history seems too short for this explanation, for the caseous nodules looked as though they must be more than a month old."

MEDICAL PRACTICE ON THE EAST SIDE.

THE University Settlement of this city has just issued its annual report, in which is set forth a statement of the work which it has accomplished in the tenth ward, and of the adverse conditions which have to be met in its endeavor to extend material and moral aid to the dwellers in this densely populated part of the city. The subreport of the superintendent, Mr. Reynolds, in which are recounted a number of evils which he describes as "important facts illustrating the accumulative influence of poverty in making the poor poorer," an interesting side light is thrown upon the conditions of medical practice in that district of the metropolis.

There are, he says, twenty-two regular medical practitioners in the tenth ward, and a few physicians practising in connection with drug stores. And then comes up the ever obtrusive dispensary abuse: "There is much complaint from the regular physicians of the ward against dispensaries and outside institutions, on the ground that the managers of these institutions often do not sufficiently endeavor to prevent imposition, and that not infrequently they give free treatment in the hope of afterward securing a pay patient."

A rival of the dispensaries, but their ally in the war upon honest physicians, is a recent importation from Russia, the feldscherer, or "felshur" as he is called in Jargon, a sort of barber surgeon whose panacea is bleeding. They do not practise openly, but are often called in at the beginning of a sickness.

"Midwives are another class of medical attendants of inferior grade. The board of health seems not to be posted regarding their number, or else to be unwilling to give the list. As there is no system of licensing them, these women are unreliable and untrustworthy. Their chief hold upon the people is the smallness of their charge. The legal requirement, that a certificate of recommendation from some physician be secured, amounts to nothing, as such recommendations are easily obtained and need not be preceded by an examination."

The drug stores are also sharply criticised: "There are thirty-three drug stores in the tenth ward. Throughout the city the average is one drug store to every physician. As there are but twenty-two physicians in the ward, it will be seen that the average is three drug stores to two physicians. Doctors having no practice will sometimes start a drug store and give their services free, expecting to get their pay in the price of drugs. As a natural result of the excessive number of such stores, competition is sharp, and, while a few of them are excellent and entirely reputable, many lead a precarious life, become a semi-medical establishment, go into the patent-medicine business, or encroach on other trades. One druggist of our ward admits that medicines are often put up at prices which make it impossible for them to be pure. One drug

store was discovered by a physician to have substituted sugar for antipyrin."

Mr. Reynolds' report shows pretty clearly that the life of the physician who has to contend with quacks, midwives, dispensaries, patent-medicine venders, and prescribing druggists is far from being a happy one.

THE LEGAL INDORSEMENT OF QUACKERY.

The success that has attended the enactment of medical laws for the different States is likely to be offset by the artful dodgers on the outside of legitimate medicine, who are endeavoring to obtain special legislation by which they can indulge in fake medical practice and still be protected against the envy, malice, and uncharitableness of the man who obtains his license after passing a State examination. Of course this is very unjust toward the wonderful healers and faith curists who cannot otherwise earn a living. As an instance of the direction in which this abominable legislation is tending, we quote a news item from a Western contemporary to the following effect:

"In an important decision made by Judge Kohler in the common-pleas court at Akron, Saturday, he holds that the Mosgrove law requiring persons to have certificates before practising medicine does not apply to osteopathy, Christian science, massage, hypnotism, or any such treatment of patients. The decision was made in the case of Eugene Eastman, an osteopathist, who was convicted in the police court on complaint of local doctors."

All this shows the necessity for committees on medical legislation to be on the lookout for the possible enactment of such laws by ignorant statesmen and by interested frauds. If such decisions are to establish a precedent, all the burdens must be borne by the regular physician and all the rewards enjoyed by the quacks.

THE PROFESSIONAL ANÆSTHETIZER.

So far as we are informed in the matter, there exists in this great city no physician who makes a specialty of administering anæsthetics. There would seem, however, to exist a demand in this direction. Surgeons are constantly at a loss to find at short notice men of experience in ether and chloroform administration, no less than in other forms of general and local anæsthesia, upon whom they can call for assistance in their important operations. The post at the head of the operating-table is an honorable one, and at times everything depends upon how ably it is filled. If the surgeon is constantly distracted in his work by solicitude and perhaps alarm for the safety of his patient in the hands of one whom he does not know as a careful giver of the gas, he may be prevented from putting forth his best efforts for the patient from the cutting side of the operation. Large surgical hospitals might at times with advantage avail themselves of the services of such a professional anæsthetizer. Not infrequently, as all operators are aware, the life of the patient, no less than the success of the operation, is jeopardized by the careless or ignorant manner in which this important part of the procedure is carried out by a *novicus* just out of the medical school. In almost all institutions it is the junior on the staff, who is going through the process of gaining knowledge and skill rather than applying that previously acquired to whom this important duty is given over.

Every surgeon is aware of the great difference in men as ether givers, and the sense of relief he feels when a good man manipulates the inhaler. Then, too, we might speak of the great saving of time, to say nothing of the saving of ether. Much more ether is usually employed by the novice than is at all necessary, and all will admit that, other things being equal, the less the patient consumes the better it is for all concerned.

The probable explanation for the fact that this important field remains uncultivated—we almost said worked—is to be sought in the unwillingness of young men to enter upon a career which would seem at first glance to offer so little for the future, whatever the emoluments of the present might be. This objection is, however, more imaginary than real, and the opportunities offered for advancement would surely be greater than in many occupations in which young physicians engage during the waiting years, such as insurance examination, inspection for health boards, newspaper work, or society reporting. Who will be the first to engage in this new specialty?

THE CHARITY ABUSE.

If the recent agitation of this question does not serve to effect some reform, more words would seem useless; still we cannot refrain from relating certain information communicated to us by a nurse who has had an extended experience in the gynæcological room of a New York dispensary. This young lady was of the opinion that the abuse of charity was particularly noticeable in this institution, and cited in proof of her opinion that, as a rule, the patients were cleanly, and their clothing and linen indicated that they were well to do. She gave considerable personal information, of which the following is an instance:

A patient, who was apparently comfortably situated, remarked in the course of conversation that she wanted Dr. ——— to perform an operation, and she did not see any use in paying him $300 or $400, when she could have his services for one dollar a month by coming to the dispensary. This was not an unusual instance, but one of almost daily occurrence. The aggravating feature is not so much the loss of the money to the individual physician as it is the loss of respect for his profession—the light esteem in which medical service is held.

Unless the evil is remedied, the time may not be far distant when progress in medical science will be greatly hindered, as men of ability will not care to enter a profession so little honored. The various schemes for remedying the evil, such as requiring certificates, appointing investigating committees, etc., ought to be entirely unnecessary. It is doubtful if such a bill as was recently introduced into the legislature would improve matters. A certificate from a

policeman or landowner would not mean anything, for policemen and landowners frequent the dispensary as well as other members of society who have no moral right to go there. While all acknowledge the necessity of the dispensary in the education of the young physician, we hold that limiting its benefits to the deserving poor would still give ample educational opportunities. It is the physician who usually learns most of the patient and is the best judge of his ability to pay, and to him should be given the power to decline treatment when it is apparently undeserved, and until the case is referred to the proper inspecting committee. It is to be regretted that there are not honor and fellowship enough among physicians to enable them to stand together in this matter; then, if there could be less rivalry between institutions, there might be some hope of bettering present conditions. It seems strange that one should take pride in the large number of paupers, sick and disabled persons that we have among us. But the truth of the matter is that the physician who attends a dispensary which can present a fine array of statistics thinks that these figures will attest his experience and increase his private practice. Charity is a very secondary consideration with him. The physician is human, and, while he may be attentive to the welfare of others, he is by no means entirely forgetful of his own. The difficulty seems to be that doctors cannot agree as to what is best for their own interest, but the sooner they learn that harmonious action will do more for all concerned than rivalry ever can do, the abuse of medical charity will be corrected without the intervention of legislature, or any other agency outside the profession itself.

News of the Week.

Congress of American Physicians and Surgeons.—This congress is composed of the members of the fourteen national societies whose joint meeting is held once in three years in Washington—on May 4th, 5th, and 6th of the present year. To enable a physician residing in the United States to become a member of the congress, with the right to participate in its proceedings, it is necessary that he be a member of one of these constituent national societies. A physician may be accredited as a visitor to the congress by any one of the constituent societies. The certificate of the secretary of one of these societies to the effect that he is thus accredited will enable him to register upon payment of the registration fee, which registration will entitle him to a card of admission to the reception and "smoker," and to a copy of the Transactions of the congress, but not to take part in the deliberations of the congress. All physicians are invited to attend the meetings of the congress and the public meetings of the societies, but only those may register who are members, specially invited guests, or visitors accredited through the secretaries of constituent societies. The registration office will be in Parlor 1 of the Arlington. From this office the mail of members and invited guests will be distributed, and here the city address of each member, guest, and accredited visitor can be ascertained. All members, invited guests, and accredited visitors should register as soon as possible. A registration fee of five dollars will be required of all members and accredited visitors. Invited guests will register, but will not pay the registration fee. A copy of the published Transactions of the congress will be sent to all members and to each invited guest and accredited visitor who is registered. Only those who register, and the ladies accompanying them, will be admitted to the reception. The president of the congress, Professor William H. Welch, M.D., of Johns Hopkins University, will deliver an address Wednesday evening, May 5th, at 8:15 o'clock, in the Columbia Theatre. The exercises attending the unveiling of the statue of Professor Gross, under the auspices of the Surgical Association, will be held on Wednesday, May 5th, at 5 o'clock. On Wednesday evening, at 9:30 o'clock, the president of the congress will receive the members, the invited guests and accredited visitors, with the ladies accompanying them, at the Arlington. On Thursday evening the Cosmos Club will give a complimentary "smoker" to the congress, which will add greatly to the social features. The dinner of the congress will be at the Arlington on Tuesday evening, May 4th.

Obituary Notes.—Dr. John C. Terrell died of pulmonary tuberculosis, at Philadelphia, on March 28th, at the age of eighty years. He was born in North Carolina, and was graduated from the University of Pennsylvania in 1840. He returned to his native State and engaged in the practice of his profession for a period of thirty years, but of late, in the management of his tobacco interests, he had lived for a part of each year in the North and for a part in the South.—Dr. J. H. Walton, of Dubuque, Iowa, committed suicide in Lincoln Park, Chicago, by cutting his throat with a razor, on Sunday morning last. No reason is given for the act.—Dr. Theodore Burr died at Detroit, on March 24th, at the age of eighty-one years. He was graduated from Geneva and Cornell Universities, and practised medicine successfully in Ulysses, Tompkins County, New York, his native village. During the Mexican war he served with General Winfield Scott and reached the rank of colonel. During the civil war he devised an iron gunboat of an entirely new style, which, with modifications by Ericsson, proved eminently successful.

Veto of a Spitting-Prohibition.—The city council of Springfield, Mass., recently passed an ordinance forbidding spitting upon the sidewalks of that city, but Mayor Dickinson has vetoed it, and the citizens of that town have still the liberty to expectorate when and where they will.

Remuneration for Reports to Health Boards.—It is announced that at last the State of New York has a law requiring municipalities to pay physicians and midwives for reporting births, and clergymen and magistrates for reporting marriages to local boards of health. The remuneration is not to be large, only twenty-five cents for each return, but the principle is

the thing to be considered. We can see no reason why physicians should not be paid for making out death certificates also.—*New York Medical Journal.*

Medical School Inspection.—The inspectors of schools recently appointed by the board of health have discovered a large number of children attending the public schools who were in the infectious period of various contagious diseases. These were at once excluded and isolated at their homes. Nearly six hundred such spreaders of contagion were found the first week of the inspection.

The Increased Duty on Imported Mineral Waters.—The leading physicians of New York, Boston, Philadelphia, Baltimore, Chicago, and other cities are petitioning the United States senate not to adopt the high rates of duty provided in the Dingley tariff bill on natural mineral waters, which are, we must suppose, the result of miscalculation. The dietetic effervescent waters and the other natural mineral waters ought to be admitted free, the same as they have been continuously for twenty-five years. As the petition states, there has been for a long time a duty on the bottles, and although the medical profession cannot very well concern itself with the question of duties on bottles in general, it properly petitions that, at least, the duty on the ordinary green-glass bottles containing these mineral waters should be a moderate one, such as existed prior to 1890. Under the present tariff these waters, although on the free list, already pay—through a duty on the bottles in which they are imported—as much as do bottled malt liquors and bottled still wines; consequently the impropriety of any increase, and especially a heavy increase, in duty on these necessary and important therapeutic aids is self-evident.

The Mental Condition of the German Emperor.—The foreign correspondents of the daily press have repeatedly referred of late to the symptoms of insanity which are said to become more marked daily in the case of Emperor William. From a physical point of view, the London *Medical Times* says: "This monarch suffers from many infirmities, viz., an undeveloped arm, an ear trouble, and bad general health. The defects alone would, in an ordinary person, be considered sufficient to account for eccentricity and want of mental balance. If one limb be undeveloped there may be a corresponding defect in the opposite half of the brain—a lop-sidedness close to some of the most important centres. The ear disease may be of an irritative character, causing irritability and uncertainty of temper. Well known and perfectly obvious as the anatomical deficiencies are, they are not taken into account as influencing emperors and personages in high places. The kaiser has not even the excuse that he is 'a self-made man who worships his maker,' but being in power, he, with a self-concentration which is remarkable, puts himself, and himself alone, as the one consideration; his ideas are transcendent and grandiose—the naval programme, to wit. He ignores counsels and counsellors; he rejects experts, and poses as one himself; a very Teufelsdröckh in being a professor of things in general. Surely such a condition cannot be a political puzzle; it must be a pathological psychological study. The personal equation was never so well shown, and never so dangerous—because respected and not discounted."

The Health of the Tsar.—*The Lancet* says that it has been informed upon excellent authority that there is no foundation for the alarming rumors regarding the health of the emperor of Russia, which have been industriously circulated during the last few months. His majesty does not suffer from any cerebral symptoms, as has been alleged; he is out every morning as soon as it is light, and keeps himself in condition by running a verst (eleven hundred and sixty yards, or about five furlongs), watch in hand, to see that he can do it in his average time. One of his amusements is said to be shooting from a bicycle, and he can bring down a crow even when he is going at a good speed. The accouchement of the empress is expected this month.

The Unreliability of Hydrophobia Statistics.—At a recent meeting of the Paris Academy of Medicine, M. Megnin pointed out that current statistics regarding hydrophobia were entirely misleading, as many dogs were declared mad when they simply had epileptic fits. He added that dogs, like human beings, seemed to be more inclined to nervous diseases than formerly.

The Late Dr. William B. Berry.—At a meeting of the Orange Mountain (N. J.) Medical Society, held March 19, 1897, the following resolutions were adopted:

"*Whereas*, This society has been informed that Dr. William Bogardus Berry died in Pasadena, Cal., in December, 1896; and

"*Whereas*, He was one of the founders of this society and for a number of years did his full share to promote its scientific advancement and social well being; therefore be it

"*Resolved*, That it is with profound sorrow that we have learned of the untimely death of our late associate, and that we desire, as a slight tribute to his memory, to have it recorded that we have never known a purer nor a more sincere man, and that his professional equipment and his private character were such that his membership cast lustre upon this society.

"*Resolved*, Further, that in his death the profession has lost a faithful and accomplished practitioner, his family a wise and devoted husband and father, the community a good citizen, the poor and the unfortunate a ready helper, and the membership of this society a genial companion and a noble and high-minded friend.

"*Resolved*, Further, that these resolutions be inscribed upon our minutes, and that copies of them be sent to Dr. Berry's family, to the *Journal of the American Medical Association*, to the MEDICAL RECORD, and to the *New York Medical Journal.*

"JOHN J. H. LOVE, M.D.
"RICHARD C. NEWTON, M.D.
"THOMAS W. HARVEY, M.D."

The Arizona Medical Association.—The annual meeting of this society was held in Phœnix on February 26th and 27th, under the presidency of Dr. D. M. Purveau of that city. The president's address was entitled "Hereditary Influences." A medical-practice bill, proposed by the Mariposa County Medical Society, was endorsed after full discussion, and is now before the State legislature. It provides for a license to practise medicine, to be granted after the applicant has passed an examining board of five physicians to be appointed by the governor. The next meeting will be held in Tucson, May 17 and 18, 1898. The following officers were elected: *President*, Dr. Charles H. Jones, of Tempe; *First Vice-President*, Dr. George W. Brockway, of Florence; *Second Vice-President*, Dr. T. H. Sabin, of Yuma; *Third Vice-President*, Dr. H. W. Fenner, of Tucson; *Secretary*, Dr. L. D. Dameron, of Phœnix; *Treasurer*, Dr. William Duffield, of Phœnix; *Essayist*, Dr. T. Shields Collins, of Globe.

A New Form of Press Notice.—The story of a diamond robbery has become stale as a form of advertisement for the well-managered actress, but it has been difficult to find an efficient substitute, and it was reserved for the original mind of Miss Loie Fuller to pose as a physiologist in order to call the public's attention to her polychromatic corporeal contortions. She recently came out in an English journal as an advocate of a purely fruit diet, which she prefers even to vegetarianism. The grounds of her preference are lucidly stated as follows: "The sugar in the sweet fruits serves the same end as starch in other things. Starchy substances must change first into dextrin and then into glucose ere they reach the stage dates and figs have already attained. The ripening process has brought them to the condition whereto starch is reduced in the human body. On this development nerve force is exhausted, and the tissues are gradually weakened, all which may be avoided by replacing starchy foods with naturally sweetened ones."

A Pasteur Institute is to be established in Baltimore by the College of Physicians and Surgeons. Dr. John Ruhrah, who has just returned from Paris after a practical course at the Pasteur Institute there, has brought with him several rabbit cords in glycerin and has already inoculated two rabbits.

The University of Maryland, founded in 1807 and one of the oldest institutions in the country, is rebuilding the University Hospital. The new buildings, which will occupy almost an acre of ground, will accommodate one hundred and seventy-five patients and will cost about $70,000. They will be built in the colonial style, to conform as far as possible to the old buildings of the University of Maryland.

The Disposal of Offal by the Reduction System, as now used in the cities of New York and Philadelphia, will shortly be recommended for adoption to the city council of Baltimore by a special committee appointed by it to investigate the subject.

The Ninth International Congress of Hygiene and Demography, which was to have been held in Madrid during the coming autumn, will probably be postponed until Easter, 1898, or else abandoned altogether. A meeting of the committee was held several months ago, at which time it was evident that the original enthusiasm of those who had invited the congress to Madrid had been extinguished by the distress into which Spain has been plunged by her ineffectual efforts to conquer Cuba and the Philippine Islands. If the congress should not be held in the spring of 1898, its session will probably be deferred to the time of the Paris exposition in 1900.

The Doctor Thrown in with the Potatoes.—A correspondent of *The Lancet* sends to that paper the following advertisement clipped from a provincial paper: "Free Medical Attendance and Medicine.—Having succeeded in engaging the services of an eminent and very successful Professional Gentleman, I offer the above to all my customers.—John Andrews, Wholesale and Retail Provision and Potato Merchant, Lincoln Road, Fratton."

Guy's Hospital, in London, made an appeal some time ago for subscriptions for an endowment fund of $2,500,000. In spite, however, of the patronage of the Prince of Wales and of earnest efforts on the part of the committee in charge, only about one-third of the desired amount has as yet been subscribed.

Free Medical Attendance in Belgium.—The physicians in Belgium who receive salaries from the State for attendance upon the poor, are complaining that the term "poor" embraces most of the inhabitants of the districts in which live not only shopkeepers and farmers but the officials as well, that is, the guardians of the poor and the communal councillors. Several of the physicians have made out a list of those to whom they are obliged to give their services gratuitously, but who are well-to-do if not rich, and they protest that if the State robs them of their legitimate *clientèle* it ought to give them a compensatory increase of salary.

Compensation for Notification.—A bill has been introduced into the legislature of this State directing the payment of twenty-five cents for each marriage, birth, or death notice made out and transmitted to the proper authorities in accordance with the existing law.

The Optometry Bill.—According to the *Albany Medical Annals*, no measure relating to State medicine, so far presented in this session of the legislature, has brought forth anywhere near the opposition that this so-called optometry bill has met with. From the moment of its introduction there has been a constant and vigorous fight against it. So far the bill has been given two hearings before the assembly committee on general laws. At each hearing vigorous pleas in opposition were heard. The objections to the bill were chiefly as follows: That none but practising physicians were competent to advise and prescribe for diseased eyes; that there was great danger to the public from irresponsible persons attempting to adjust glasses; that it would license to practise upon an

ignorant public a large class of designing and unskilled men who know nothing, and are not required to know anything, about the diseases of the eye, or the underlying pathological conditions of the body which are often the direct cause of derangements of vision. The Albany correspondent of the *Evening Post* reported some time ago that it was understood the bill was to be killed in committee.

The Spanish Losses in Cuba.—The following harrowing description of the condition of Spanish troops in Cuba comes from Madrid. The latest alarming reports received from Cuba go to prove that the strength of General Weyler's troops has been brought to a startlingly low figure. Fully eighty per cent. of the troops are composed of mere boys from seventeen to twenty-four years of age, who were ordered out to Cuba after receiving from six weeks' to two months' military training in barracks. Each battalion left the Peninsula one thousand strong, yet at the end of November one of them at Candelaria, in the Province of Pinar del Rio, was reduced to three hundred and twenty men, and this is a comparatively high figure; another battalion mustered no more than eighty-two men. One column went to the front having four thousand men, and in a short time it dwindled down to eight hundred men. "The same thing," writes Señor Pena, "has occurred on a higher or lower scale throughout the army." As for the hospitals they are stated to be in a very bad condition. There are, of course, many members of the medical staff who do their very best for the wounded, but their laudable efforts are practically lost owing to the disorganization prevailing everywhere, the want of food, drugs, surgical instruments, beds and bedding in the pestiferous houses and shanties called hospitals, where the wounded are packed together and often exposed to rain, wind, and cold.—*British Medical Journal.*

Pathological Section of the Moscow Congress.—The following are the titles of subjects proposed for discussion before the pathological section: the botanic specificity of pathogenic microbes; the pathology of thrombosis; the origins of different forms of diabetes; the pathology of myxœdema; the rôle of antitoxins in the production of artificial immunity; the pathology of inflammation and the parts played by blood-vessels and parenchyma. All correspondence with regard to the section should be addressed to M. G. Dourdouñ, Pretchistinsky Boulevard, Jerusalemskoe Podvorie, Moscow.

Philadelphia Neurological Society.—A stated meeting of the Philadelphia Neurological Society was held on March 22d, the president, Dr. C. W. Burr, in the chair. Dr. A. A. Eshner exhibited a case of probable basilar meningitis in a man with Argyll-Robertson pupils, absence of knee jerk, uncertain station, impairment of sensibility, optic neuritis with beginning atrophy, a little awkwardness of speech, and unilateral sweating. Dr. Charles K. Mills exhibited a case of rather coarse tremor associated with athetoid movements in a growing girl whose birth had been attended with difficulty; and also a case of nodding and rotatory movement of the head with tremor of the hands, in a man in middle life whose father living at an advanced age was said to present a similar manifestation. Dr. A. A. Eshner exhibited a case of congenital tremor of intention type, unattended with spastic phenomena, speech disturbance, or nystagmus. Dr. A. G. Thomson read the report of an exceedingly interesting and unique case of isolated traumatic bilateral paralysis of the abducens nerve. The lesion was believed to be a laceration or rupture of the nerves from stretching as a result of violence by contrecoup. Dr. Joseph Leidy reported a case of dysphagia and dysphasia resulting from a focal lesion of the internal capsule, and one of profound nervous phenomena from malarial infection; he also read a note on neuralgia of the cranial nerves as a symptom of neuralgia.

The Osteopaths have secured the introduction of a bill in the North Dakota senate, authorizing "any person having a diploma regularly issued by the American School of Osteopathy, of Kirksville, Mo., or any other legally chartered and regularly conducted school of osteopathy, who shall have been in personal attendance as student in such school for at least four terms of not less than five months each before graduation, to treat diseases of the human body according to such system." This new "science" rests upon the belief, so we are assured by those who presume to know, that all disease is due to a fracture or dislocation of some bone, to dislocation of a tendon, or to misplacement or compression of an artery. The treatment of all diseases naturally consists, therefore, in replacing the dislocated structure. It seems to be a sort of widening of the field of the bonesetter. The manipulations of its professors may afford diversion to the cowboy with a pain, but we fear they will meet with little favor with the tenderfoot of the effeminate East.

Brotherly Love in Kansas.—The Regular, Homœopathic and Eclectic State Medical Societies of Kansas are all to meet in Topeka this year, and all at the same time. Some one who is desirous of promoting peace has suggested that a joint meeting of the three societies be held one day during their sessions.

Woman and the Bicycle.—The *Medical Age* of Detroit has become an ally of the *Dominion Medical Monthly* in the fight upon the bicycle for women, as shown in an editorial in the first-named journal. The *Age* follows the same line of argument in substance regarding the "saddle," "pedals," "erotism," "erethism," "orgasms," and like vulgarities. There must be something particularly singular about the conditions prevailing in the beautiful lake cities of Michigan and Ontario that needs investigation.—*Kansas City Medical Record.*

Clinical Reports by Phonograph.—The St. Louis *Clinique* announces that it will hereafter contain reports of clinical lectures recorded by the phonograph. It says very truly that busy "surgeons and physicians will not take the time to write out reports of their lectures, and they are always irritated by mistakes made

by shorthand writers, who generally are not familiar with medical terminology. Now we have them just where we want them. The phonograph tells 'the truth, the whole truth, and nothing but the truth.'" The March number contains the report of a lecture by Prof. Waldo Briggs, received in a phonograph.

Fifty-Cent Hospitals.—There is vigorous war being waged in St. Louis against several hospital associations in that city, which advertise to give medical advice, medicines, and a bed in the hospital to all members of the association who will pay fifty cents per month. From an *exposé* of their methods by Dr. Lanphear (*American Journal of Surgery and Gynæcology*), we extract the following part of a section of the prospectus of one of these: "This association contracts to give you the advice of eminent and able physicians and surgeons when needed, all the medicines you may require for any ailment you may have, or when you are ill or meet with accident to admit you to a first-class hospital, where you will be carefully attended and cared for. The association agrees, in addition to medical and surgical advice and medicine, to provide you with bed, board, and educated and trained nurses, who will give you the most careful attention, and who will see that the medicines prescribed by the physicians are given just as directed by him, and will also render those little attentions so necessary to the sick and injured. You are offered all these advantages for the small sum of fifty cents per month, with the assurance that there is positively no extra charge for anything you may require." Some of the other hospitals are more liberal than this, for they agree to send a physician to the patient's house in case he is confined to his bed and does not care to go to the hospital. The names of some well-known St. Louis physicians are published as being the physicians of these associations, who are ready to treat the subscribers for as much of the fifty cents a month as may remain after the other expenses of the business are paid. We have a "Medical Treatment Company" in New York, but it is an expensive concern compared with the St. Louis hospitals, for the cost of membership is $1 a month, and hospital treatment is not thrown in. If we can judge of worth by price, medical treatment in New York must be one hundred per cent. better than it is in St. Louis.

The Collection of Vital Statistics.—A bill has been introduced into the North Dakota legislature to provide for the collection of vital statistics. The superintendent of each county board of health must obtain and register the usual data concerning births and deaths. The parents must give notice of the births and deaths of their children; every householder must give notice of every birth and death occurring in his house; the oldest person next of kin must give notice of the death of any of his kindred; the superintendent of every institution must give notice of births or deaths occurring in the institution under his charge; a physician must report the death of any person under his professional care; and physicians and midwives must report the births occurring in their practice. For each birth or death reported the county treasurer is required to pay the sum of ten cents, the accounts being settled semiannually.

Pathological Society of Philadelphia.—A stated meeting of the Pathological Society of Philadelphia was held on March 25th, the president, Dr. J. H. Musser, occupying the chair. Dr. Joseph McFarland exhibited phleboliths from the pelvic veins of a case of malignant disease; also a heart the seat of malignant endocarditis, with perforation of an aortic leaflet; a spleen with multiple infarction, and a granular kidney. For himself and Dr. J. M. Anders, Dr. McFarland exhibited an annular carcinoma of the sigmoid flexure of the colon. Dr. G. A. Muehleck exhibited a hand that had been amputated on account of carcinoma of the thumb. Dr. D. Riesman exhibited a specimen of intussusception from an infant fifty-four hours old; also a specimen of amyloid degeneration of the suprarenal body. Dr. A. E. Taylor made a verbal report upon the state of the blood in a case of trinitrobenzol poisoning. The red corpuscles appeared not to be destroyed, although their chemic composition gave evidence of being altered. Dr. H. L. Williams exhibited a dermoid cyst removed with the uterus by Cæsarean section from a woman in labor. Dr. J. P. Crozer Griffith made a demonstration of Kayserling's method of preserving the color of pathologic specimens, which consists in the employment of alcohol and formalin, glycerin, potassium nitrate, and potassium acetate, in solution. Dr. D. Riesman exhibited the stomach presenting only amyloid disease, from a case of rumination; also hypoplastic lungs weighing together eleven ounces from a case of meningitis. Dr. A. A. Eshner exhibited for Dr. O. H. Allis a foot amputated on account of suppuration of the ankle-joint.

Bottled Air.—Among the miscellaneous articles in the *North Carolina Medical Journal*, January 5th, we read that a French chemist, Linde, has invented a process for condensing air to such an extent that it will contain seventy instead of twenty-five per cent. of oxygen. It is proposed to bottle mountain and sea air, and furnish it to invalids at their homes. It will be recalled that years ago a Vienna physician treated his patients with the bottled air of mountainous health resorts supplied at their homes. It is to be presumed that the physician profits more than the patient from this method of treatment.

A Railway and Navigation sanitary conference will be held at Brussels, some time in September next. For information address the secretary, Mr. M. J. de Lantsheere, Rue de l'Association, No. 56, Brussels.

The German Surgical Congress.—The twenty-sixth congress of the German Surgical Society will be held in Berlin on April 21st and three following days, under the presidency of Professor Bruns. The questions proposed for discussion are: 1, The surgical treatment of gastric ulcer; 2, the use of the Roentgen rays in surgery; 3, the operative treatment of hypertrophy of the prostate. A report on the collective investigation now being prepared on anæsthetics throughout Germany will be presented.

Reviews and Notices.

TRANSACTIONS OF THE AMERICAN DERMATOLOGICAL ASSOCIATION, at its Twentieth Annual Meeting, held at the Hot Springs of Virginia September 8, 9, and 10, 1896. Official Report of the Proceedings. 1896.

THIS is in reality a reprint of such of the transactions as were published in the *Journal of Cutaneous and Genito-Urinary Diseases*. Short abstracts of the papers are given, but where the originals are to be found is not indicated; hence the value of the discussions is materially decreased. Those who read the report of the meeting in the RECORD will find little or no need for the official transactions. It is to be regretted that after the somewhat elaborate illustrated reports which the society has been publishing during the past few years it should have been found necessary or expedient to take so backward a step.

HOPKINS' POND AND OTHER SKETCHES. By ROBERT T. MORRIS. G. P. Putnam's Sons. 1896.

THE author of these charming sketches has done a service to his fellows in rescuing the tales from the files of various papers where they were lying buried. They deal with scenes of hunting and fishing, and exert a refreshing and tonic effect, even on one to whom they do not call up personal experiences of a like nature.

THE AMERICAN IN PARIS. A Biographical Novel of the Franco-Prussian War; the Siege and Commune of Paris. From an American Standpoint. By EUGENE COLEMAN SAVIDGE. Second Edition. Philadelphia: J. B. Lippincott Company. 1896.

THIS is an account of the stirring times in Paris a quarter of a century ago, told under the guise of a romance. It is interesting and historically correct in all essentials. We are glad when physicians undertake other than professional tasks to see them fulfil them so well as Dr. Savidge has done in this instance.

STATE BOARD OF HEALTH OF MASSACHUSETTS. Twenty-Seventh Annual Report. Boston: Wright & Potter.

THIS report contains over eight hundred pages, and, as usual, is given up mostly to water supplies, the examination of rivers, disposal of sewage, and statistics. There is a short chapter on the production and use of antitoxin.

THE DISEASES OF INFANCY AND CHILDHOOD. For Use of Students and Practitioners of Medicine. By L. EMMET HOLT, A.M., M.D., Professor of Diseases of Children in the New York Polyclinic; Attending Physician to the Nursery and Child's and the Babies' Hospitals, New York; Consulting Physician to the New York Infant Asylum and to the Hospital for the Ruptured and Crippled. With Two Hundred Illustrations, including Seven Colored Plates. New York: D. Appleton & Co. 1897.

THE author may justly claim for his work that it is limited, as nearly as may be, to the discussion of those affections which are peculiar to infancy and early childhood and to the modifications of diseases as they affect those of tender age. The work is a very extensive one, and indicates a wide field of research, as well as an experience which has been profitably utilized. Naturally, writers on pædiatric subjects have been largely drawn upon, but the author's personality pervades the whole text. In spite of over one thousand pages of text, omissions have occurred, and some branches are not at all exhaustively treated. On the other hand, the chapters on nutrition changes and disorders, the pathology and anatomical lesions of disease, and the clinical observations of a statistical nature are full, and show hospital and dead-house observation of wide range, if not extending over so many years as that of some recent writers on the same subjects. We must bear in mind that pædiatrics as a separate branch is in itself a rather modern specialty, and one who has made as much of it as the author of this work deserves all the credit his work will bring him. Infant feeding and questions of hygiene have been entered into largely, as their importance requires, and all that is new and good in these departments has been carefully presented.

The illustrations are numerous, and have been taken principally from original cases, while those borrowed from outside sources have been selected with good judgment.

As a whole, the work is to be looked upon as a rich contribution to the literature of infantile symptomatology, pathology, and therapeutics. Its real utility centres in its practical character and its wide adaptability to the needs of the general practitioner.

OVER THE HOOKAH; THE TALES OF A TALKATIVE DOCTOR. By G. FRANK LYDSTON, M.D., Professor of Genito-Urinary Surgery in the Chicago College of Physicians and Surgeons; Professor of Criminal Anthropology in the Kent College of Law, etc. Fred Klein Company, Chicago.

WE have read with much pleasure the interesting and well-told stories in this book. It is not always that a good *raconteur*, such as the author is known to be, is equally facile with his pen and can put his stories on paper without spoiling them. But this Dr. Lydston has succeeded in doing. The stories are naturally not all of equal merit, and most of them, like nearly everything that is written, would be improved by condensation. But they are entertaining, and will help, when read, as they were told, to an accompaniment of the bubbling hookah, to tranquillize many a brain wearied with life's little (or great) anxieties. The writer is an ardent devotee (we trust not slave) of Nicotiana, and each story is preceded by a metrical invocation to the object of his cult.

Clinical Department.

OPERATION FOR OBSTRUCTION OF THE BOWELS.

BY J. D. BUDD, M.D.,

TWO HARBORS, MINN.,

CHIEF SURGEON, DULUTH AND IRON RANGE RAILROAD.

AT 9 P.M., December 24, 1896, I was called by Mr. S—— to see his son, a boy, sixteen years of age, who the father said was suffering with cramps, vomiting, and inability to pass urine. On arriving I found the patient in great pain and unable to keep anything on his stomach. After examination I told the father that I thought the trouble due either to obstruction of the bowels or impaction of fæces, and the inability to pass his urine due to the pressure of the obstructing mass against the neck of the bladder. I ordered enemas of soap and water, and remained to aid in the giving of them. After one or two injections had been given we got a few scybalous masses and the patient passed urine. I then gave enemas of sweet oil, glycerin, and water, at intervals of half an hour, until the scybala were all removed and no nodular masses could be felt. At this time, two o'clock at night, he passed a very little flatus, and I felt so encouraged I gave him a dose of Carlsbad salts in hot water and went home.

On Christmas Day I called to see the patient and found that he had had no further movement of the bowels, that he was still vomiting and suffering greatly. I gave one or two large enemas, without result. About noon the stercoraceous character of the material vomited convinced me that the obstruction was complete and an operation absolutely necessary.

The parents consenting, I telegraphed to Dr. A. C. Taylor, of Duluth, to come to Two Harbors immediately and assist me in the operation. Dr. Taylor agreed with me as to diagnosis and the imperative need of an immediate operation. It was nearly midnight when all preparations were completed. Dr. C. A. Anderson gave the ether, and Dr. Taylor assisted me in the operation. We made the incision in the median line below the umbilicus and entered the abdominal cavity. We found the obstruction in the ileum at Meckel's diverticulum, about two feet from

the ileo-cæcal valve. There was a large perforation in the diverticulum, and in nature's attempt to wall it off a large quantity of inflammatory lymph was thrown out, with the result that the two loops of intestine were adherent for several inches, completely covering in the perforation and producing the obstruction. As soon as the adhesions, which were evidently of recent date, were broken up and the ileum was straightened out, the contents of the bowel began to pour out through the perforation. I immediately grasped the bowel at this point and covered it with my thumb, while Dr. Talyor resected about six or eight inches of the inflamed ileum that caused the obstruction. After examining the appendix, which was perfectly normal, and assuring ourselves that there was no further trouble, we united the two ends of the bowel with the Murphy button, replaced the intestines, and closed the abdominal wound. The patient was on the table one hour. Temperature at time of operation was 103° F., and in less than twenty-four hours it was normal; pulse, 99.

December 26th, 27th, and 28th, under one-fourth-grain doses of morphine every eight hours, the patient rested fairly well. The third day after the operation, on insertion of the long rectal tube, he passed the first flatus. Temperature, 100° F.; pulse, 80, full and strong. Liquid diet.

On December 29th flatus was passed freely and there were two very slight movements of the bowels. Temperature, 99° F.: pulse, 80. The bowels moved several times each day up to January 3d.

From January 4th to January 9th the bowels did not move, neither did the patient pass flatus, and during this interval the patient suffered intensely with colicky pains. There was no tympanites at any time and the pains seemed to be due to peristalsis. I passed the long rectal tube and gave a slight enema, but it could not be retained. Dr. Taylor came up on the 6th, and we gave the patient chloroform and passed the high rectal tube, and gave an enema of two and one-half quarts of water. It was not retained and we repeated it immediately, with better results. A slight amount of flatus was passed, and considerable amount of mucus came away with the water, but no fæcal matter. Temperature, 100° F.: pulse, 86.

On January 7th, there being no tympanites and the patient suffering from colicky pains, I administered choroform and gave another large enema of two and one-half quarts of water, with no better results than before. There was some mucus in the water, which was slightly stained with fæces. Temperature, 98° F.: pulse, 80.

The following day the condition was the same, with the exception of nausea and vomiting, which we attributed to the chloroform.

January 9th was the turning-point. He had, during the day, ten good and thorough movements of the bowels, and from this time on he did not have a particle of pain or a bad symptom.

On January 13th, after four days of liberal diet, I gave him an injection without chloroform, and he had a good and thorough movement of the bowels and passed the button.

There were two special points of interest in this case: First, the very large diverticulum with perforation, which resembled the perforation often found in the appendix. This perforation was about one-third of an inch in diameter. Second, the intense colicky pains with which the patient suffered from January 4th to January 9th.

We wrote to Dr. Murphy, inquiring the probable cause of these severe pains, and received a reply from him stating that he considered them due to peristalsis as the button was moving from the point of anastomosis to the colon. This we found to be the case.

At this date, January 27th, the patient is perfectly well and able to be about.

The *sine qua non* in obstruction of the bowels is an early diagnosis and operation. If opiates are given, the symptoms are masked and diagnosis is made too late to save the patient's life.

GUNSHOT WOUND OF THE KIDNEY.

By U. S. BIRD, M.D.,

TAMPA, FLA.

On the night of December 5, 1896, I was called to see a negro man with a history of having been shot. On my arrival I found a man apparently about forty years old, in good physical condition. His temperature was normal; pulse between 70 and 80. He complained of a pain in his right side. On exposing him there was seen a small wound on the right side, below the margins of the false ribs. In the back was another wound similar to the first, and occupying the same relative position. There was some tenderness in the regions of the wounds, but no general abdominal pain or distention. His clothing was stained with blood, which was still oozing from both wounds. He gave a history of having been shot about 6 P.M. on the same day, his assailant being distant some ten or twenty feet in front of him. On receiving the wound he wheeled around, but did not fall. He walked to a physician's office, received some advice, and then went to his home, where I found him about 10 P.M. When I saw him he was in pain, but suffering less than he had been. He had never vomited, but I learned that his bowels had moved several times, the movements being in great part liquid blood. The vessel had been emptied, so that I had no opportunity of seeing the contents. In view of the history, I gave a serious prognosis, and advised an operation as the only treatment which offered a reasonable chance for recovery. Owing to the unseasonable hour and the surroundings, an operation was impracticable then, but I left general directions for preparation, and promised to attend to him as early as possible next morning. Before leaving I gave him hypodermatically one-fourth grain of morphine sulphate and one-one-hundred-and-fiftieth grain of atropine sulphate.

Next morning the preparations were completed by 10 A.M. The patient's condition was better than when I first saw him. He had a slight elevation of temperature, pulse and respiration were normal, and the other symptoms were improved. Had it not been for the history I should have declined to operate. As a precaution a catheter was passed, and about an ounce of clear urine was drawn. With the assistance of Drs. W. P. Lawrence and B. G. Abernethy, I began to operate. A free incision was made in the median line. The abdominal contents were carefully examined, but no injury was seen. In order to avoid neglecting anything in the cavity which could by any chance be wounded, a lateral incision in the direction of the ascending colon was made, and the cavity and contents were again carefully inspected, with a negative result. Near the flexure at the upper part of the ascending colon an extravasation was seen behind the peritoneum, but no wound was found in the peritoneum. The search was finally abandoned, and the abdomen was closed. We were in much doubt as to the injury sustained and the result. Undoubtedly the extravasation was due to the injury inflicted by the bullet, but we could only speculate as to what other harm had been done. We thought it probable that the posterior surface of the ascending colon might have been injured, accounting for the reported appearance of blood in the stools. In that case we concluded that the worst re-

sult would be a fæcal abscess, which would discharge through the bowel, and, in view of what had been done, it was best to let it alone.

After the operation the man's condition was good, there being but little shock. About 4 P.M. I found him doing as well as could be expected. Temperature, +99° F.; pulse, about 80; respirations, about normal; no nausea. Before my arrival he had been in much pain, but was easier when I saw him. I repeated the morphine, and left directions for his care during the night. About 10 P.M. I was told by telephone that he had died suddenly a few minutes before, after an apparently convulsive seizure.

About 9 A.M. next day I made a post-mortem examination, Dr. Lawrence assisting, and Dr. Abernethy arriving just after the examination was finished. The bandage was bloodstained. On opening the abdomen the peritoneum presented a normal appearance. There was a small quantity of bloody liquid in the pelvic cavity. The original incisions were enlarged and the abdominal contents were carefully inspected, no peritoneal lesion being seen. The entire surfaces of the colon and duodenum were then exposed, no injury being found. The post-peritoneal extravasion was now examined, the connective tissue and blood composing it being torn away. When this was removed it was seen, to a great extent, to have surrounded the right kidney. When this was liberated it was found to have sustained a penetrating wound near the centre of the anterior surface, the bullet destroying that part of the organ and laying it open to its outer or right border. The pelvis was not opened.

The case is interesting because of the difficulty we had in making a diagnosis. The blood in the vessel was from the kidney, and could probably have been recognized as such if we had seen the dejections. The presence of clear urine in the bladder, however, completely misled us. That urine was drawn about sixteen hours after the infliction of the injury, a point it may be well to keep in mind in suspected wounds of the kidney. Another fact of interest is that the anterior surface of the kidney was penetrated from the front, and the peritoneum was not injured.

THE CLINICAL HISTORY OF AN ANENCEPHALOUS MONSTER.

By MARK I. KNAPP, M.D.,

NEW YORK.

With the following history I hope to contribute a clinical picture which may suggest a slight hint as to the etiology of the subject of this article.

Mrs. Fanny K——, aged eighteen years, married six months, came to me on November 4, 1894, with the following history. She aborted seven weeks ago, at about her eighth week of pregnancy; is now three weeks past her last expected menstruation, and complains of frequent micturition, has fainted twice, vomited, has headaches, pain in the left iliac region; bowels regular.

On April 1, 1895, I was called in to see her about 2 P.M. She then had pains about every half-hour. On examination I found the os allowed my examining finger with much ease, but was too small for two fingers. I advised rest in bed, and gave her opium. I was called in again on the following morning at about eight o'clock. The pains had become more frequent. Upon examination I found the os to be well dilated, greater than the size of a silver dollar. Having now satisfied myself that labor had set in, my next step was to diagnose the position of the child. Here I met a stumbling-block. Hard as I tried, I could not determine it, either by internal or external manipulation. Aside from a large, full abdomen, visual examination revealed nothing abnormal. The vaginal examination was successful in a negative way, namely, in proving that it was not the head that presented. Through the intact membranes I felt a body of the shape of an obtuse cone, which receded from my fingers as I tried to make out its nature. The abdominal examination gave me much less information as to the position of the child. Palpation elicited pain of different gradation, with the acme in the right iliac region, where even lightly touching the skin made the patient give unmistakable symptoms of great tenderness. Auscultation gave the placental bruit on the left side below the umbilicus, but of the fœtal heart I could not discover the slightest sound. I now waited, examining the patient vaginally occasionally, only to assure myself that the labor was slowly progressing. At 12:30 P.M. the membranes ruptured. A large amount of amniotic fluid escaped. Near the posterior commissure a cone-shaped body appeared, in front of which was a bladder-like structure of a greenish-yellow appearance, with fluid in its cavity. What was it? Meditating over the possibilities, to my horror this structure burst, ejecting a fluid of the color and consistency of urine. Was it urine? Had the patient's bladder ruptured? To increase my distress, a piece of that structure tore off. I smelled the ejected fluid—no urinous odor. I now examined the piece of the membrane that was torn off. It was of a light yellowish color, merging into green, translucent, waxy looking, and in consistency it was neither hard nor soft nor gelatinous. It looked very peculiar for the bladder, but what else could it be? For, although the fluid did not smell like urine, yet its color seemed to betray it. In my despair I sent for another physician, but before assistance came the fœtus was expelled and the entire phenomenon was explained. The cone-shaped body was the right knee of the fœtus, and the bladder-like structure in front of it the partly macerated abdomen of the fœtus. The macerated abdominal wall was cut by the anterior commissure of the vulva, which acted like a sharp knife, and through the divided abdominal wall protruded the enlarged liver of the fœtus. The placenta came rapidly enough, and, when I tried to extract the membranes by twisting them into a cord, a gush of blood caused me to introduce my entire hand into the uterus, in the absence of other means to still the hemorrhage. Assistance now came, and what seemed to be another placenta was expressed. Again going into the uterus, a piece of placenta was found adhering to the right side, the same side that caused the patient to have so much pain, which at that time suggested to me the possibility of local peritonitis, which certainly was present. The piece was removed and the uterus washed. The placenta was of a brown color merging into gray, of a very friable consistency and diseased.

Now as to the description of the fœtus: The body in length is nine and one-half inches, and quite fat. The face ends at the orbital plate of the frontal bone. The cranium is absent, and its place is covered with a thin, reddish-brown membrane, which was adherent to that part of the placenta which adhered to the uterus. The upper extremities are normal. There are syndactylus of the fourth and fifth toes of the right foot, ascites, and an enlarged liver of the following dimensions: transverse diameter, two and three-eighths inches; longitudinal diameter, two and three-fourths inches; antero-posterior diameter, one and five eighths inches. A microscopical examination of the liver showed interstitial cirrhosis. Spina bifida.

The treatment during the puerperium was chiefly (the record of her temperature and medication was lost) a hot-water bag constantly for five days, vaginal injections, some quinine, and a little opium. On the

third day after her confinement symptoms of septicæmia developed, but were fortunately combated. For two weeks she was confined to her bed, and made a good recovery. On May 19th she visited me and showed me the peeling off of the skin of her abdomen and her legs, which she stated had commenced during her confinement.

In seeking the cause of such a monstrosity, syphilis suggested itself, but both direct and indirect examination of both parents revealed nothing of more significance than a former simple gonorrhœa of the youthful husband.

Being a preacher of abstinence, I counselled the young couple to exercise self-denial, with such exceedingly good effect that exactly eleven months later, on March 2, 1896, I delivered the same patient of a healthy boy.

Could not the entire phenomenon of anencephaly, together with its pathological conditions—viz., the local peritonitis on the right side, the adherent placenta on the right side, the head of the fœtus adhering by a thin membrane to the right side, and perhaps the syndactylus on the right side, all appearing on the right side without any organic lesions traceable in either of the parents—be plausibly considered as the effect of an appendicitis during pregnancy, the symptoms of the appendicitis having been masked by symptoms of pregnancy?

CHOLECYSTENTEROSTOMY FOR MALIGNANT DISEASE, WITH UNEXPECTED RESTORATION OF FUNCTION.

By F. H. PECK, M.D.,

UTICA, N. Y.

The facts that we are taught not to operate in disease of the gall bladder accompanied by pronounced cholæmia, and that in cases of complete and prolonged occlusion of the cystic duct resulting in an accumulation of clear limpid fluid (probably decolorized bile) a restoration of function is precluded, lead me to report the following case, in the belief that its results are unique:

Mr. Edward H——, of Boonville, N. Y., aged sixty-six, native; admitted to Dr. Booth's service at St. Luke's Hospital, Utica, N. Y., October 20, 1896, giving the following history: About ten months prior to admission he began to suffer what he describes as gnawing pains in the epigastrium, together with progressive emaciation, though possessed of a good appetite. About six months later he commenced to develop jaundice, and noticed a tumor forming in the right hypochondrium, the epigastric pain increasing and extending into the region occupied by the tumor. He states that in the interim he has taken ten grains of calomel daily, and, in the aggregate, seven pounds of phosphate of sodium.

Status præsens (at date of admission): He is a tall, haggard man; height, six feet in stockings; weight, one hundred and nineteen pounds; intensely icteric over the entire body, with marked cachexia; gait feeble and uncertain; skin covered with nail marks, self-inflicted for the relief of the intolerable itching; with mental hebetude, subnormal temperature, ranging from 97° to 98° F., and only once during the week prior to operation becoming normal; pulse, weak in character, 64 to 68 in rate. On uncovering his abdomen a prominent tumor is noticed, protuberant beneath the thin abdominal walls, extending from the right hypochondrium to below McBurney's point, pear-shaped in outline, its lower extremity freely movable beneath the abdominal parietes, its upper extremity attached firmly to the lower border of the liver. The liver is enlarged markedly downward, its lower margin being about two and one-half inches below the free border of the ribs.

Diagnosis: Cancer involving the ducts, possibly complicated by biliary calculi.

The patient's condition was frankly explained to him, and the statement made that operation would be hazardous and with little prospect of relief other than what might result from emptying the distended viscus. He answered that he was willing to accept the hazards of operation for the small promise it held out, as his life was now too truly miserable for him to care to prolong it under present conditions.

On October 27th operation was performed by Dr. W. H. Booth, assisted by Drs. Peck, Stump, and Campbell, with a view to making a cholecystenterostomy. Section was made over the tumor from the hepatic margin to below McBurney's point. All the tissues were deeply jaundiced, the omentum looking like a yellow rag. The tumor was lifted out of the incision, tapped with a cannula and trocar, drawing off over a quart of bile, which by long retention had clarified itself of its coloring matters, all of the first portion drawn off being clear and limpid as water, while that in the bottom of the sac was full of precipitated flakes, of the color and appearance of coffee grounds. The walls of the gall bladder were healthy, and the viscus was firmly attached to the inferior surface of the liver throughout their region of contact. The liver was hard, almost cartilaginous in consistency. The region surrounding the ducts was a hard cancerous mass, and a tumor the size of a large hen's egg was felt in the adjacent mesentery. The gall bladder was incised and a Nélaton's probe was passed within, directly backward toward the spinal column, to a distance of between seven and eight inches, without encountering calculi. In view of the fact that the bile had been imprisoned long enough for a separation of its elements to occur, with probable occlusion of both hepatic and cystic ducts, the question was discussed whether it would not be better to make a biliary fistula at the incision of the abdominal wall, abandoning the idea of anastomosis with the intestine; but as the patient was bearing the operation well, and as the anastomosis would not greatly increase the hazard, and emptying the distended bladder might alter the anatomical relations sufficiently to allow the admission of bile again, it was decided to complete the operation as originally proposed. With a good deal of difficulty a loop of small intestine was found and brought outside the incision. Anastomosis was easily made with the smallest Murphy button, supplemented with a number of Lembert anchoring-sutures of fine silk; the viscera were returned to the abdominal cavity, the abdominal incision was closed with silkworm gut without drainage, dusted with iodoform, and the usual dressing applied.

The patient left the table with a good pulse, rate 75, and no apparent shock; recovered from ether without nausea, received one-fourth grain of morphine sulphate by hypodermic, and slept seven and one-half hours.

From this time his recovery was as surprising as gratifying. His temperature touched 101° F. for a brief period on October 28th, and after that ranged between 98.6° and 99.6° F. October 31st he was given two drachms of magnesium sulphate by the mouth and one and one-half ounces by enema, followed by two fæcal evacuations, the latter being bile stained. The cutaneous itching, which had been extremely annoying prior to operation, had nearly ceased at this date, and the icterus was already markedly fading. From this date he has had daily bile-stained evacuations. The abdominal sutures were removed on the tenth day after operation, the wound being thoroughly healed, and on the following day he passed the Murphy button per

rectum. He was allowed to be out of bed from the fourteenth day, when his jaundice had almost entirely cleared up. He was in a weak, listless, and apathetic condition until near the end of November, though he was sitting up and walking about the ward and slowly reawakening to an interest in life. Since early in December his mental and physical condition has shown great improvement; he has been out of doors and about the streets, and perfectly comfortable, save for recurrences of the epigastric pain due to the malignant growth. This pain is entirely controlled by infrequent doses of one-fourth grain of morphine. Up to date, January 13, 1897, he has had no return of the jaundice and the faces continue stained with bile.

It has been the good fortune of the writer to have had this patient under observation so long since his recovery, from the fact that he has no home to which he can return.

EUCAINE IN ATROPHIC RHINITIS.

By THOMAS H. SHASTID, A.B., M.D.,

GALESBURG, ILL.

Eucaine, unlike cocaine, possesses the property of dilating the vessels of the nasal mucous membrane. This vascular dilatation I have often noted, and I have found that it begins promptly, that it is well marked, and that it lasts a long time. Reflecting upon this effect of the drug, and upon the further fact that in atrophic catarrh the nasal mucous membrane is thin, pale, and poorly supplied with blood, I thought that possibly eucaine might be of service as a means of treatment in this disease. I accordingly tried it in a number of cases, of which I report only one, seeing that that one is typical of all.

Woman, aged thirty-five. Had had atrophic rhinitis since childhood. Had been treated before, and was using, at the time she came to me, a spray of Dobell's solution. The nasal mucous membrane was exceedingly thin and parchment-like. A five-per-cent. solution of eucaine was applied freely every day for three weeks. Under this treatment the mucous membrane became fuller and more vascular. The formation of crusts was much diminished, so that the Dobell spray did not need to be used with anything like the former frequency. The use of eucaine was continued three weeks longer, but no further improvement took place. Massage by means of Freudenthal's vibrator was then applied for two months, and the ultimate result was highly gratifying, crust formation being kept in abeyance merely by the use of Dobell's solution every second or third day.

In the other cases, improvement was no less marked than in the case reported. It is worth while to note also that in every case such results as could be secured by eucaine were secured in a very short time, after which further good results could indeed be secured, but only by the application of other means of treatment. The ultimate results in every case were unquestionably better than in any case I have ever treated in which I did not use eucaine.

At the last meeting of the American Laryngological Association, Dr. G. A. Leland recommended the use of cocaine in the treatment of the disease under consideration. But the hyperæmia caused by cocaine is only secondary, and, moreover, is not very strongly marked, while the increase in blood supply following the use of eucaine is very decided, and presents itself both early and late. Furthermore, in the use of cocaine there is vastly greater liability both to acute poisoning and to the formation of a disastrous drug habit.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting April 1, 1897.

Edward G. Janeway, M.D., President, in the Chair.

The Relation of Diseases of the Skin to General Conditions.—Dr. L. Duncan Bulkley read the paper. Brief mention was made of the advantages and necessity of dividing medicine into specialties. This, however, too frequently resulted in narrowness of thought and practice, especially, Dr. Bulkley thought, in connection with diseases of the skin. Lesions of the skin were too often regarded as specially local, unconnected with the condition of the general system, even when they were largely or entirely dependent upon this. The feeling was commonly shared by the patient, who frequently said he was quite well except for the skin lesion. Considerable support was given this view by the effects of local treatment, for benefit might result from such treatment even when the cause of the trouble was at a distance or systemic.

But there were certain lesions of the skin which were purely local, among which were atrophic and hypertrophic diseases, new growths, animal and vegetable parasitic diseases, etc. But even in these attention would reveal elements to which the broad principles of general medicine should be applied. A striking example of this was ringworm in children, which yielded much more readily to local treatment when certain internal agents were employed.

The facts mentioned were emphasized by citation of analogous ones seen in the vegetable kingdom. It being observed that peach trees did not bear fruit because of a parasite on their leaves sapping their vitality, the leaves were sprinkled with a poisonous fluid. But the success was not so great until the roots were given strength by special fertilizers. At his country home was a pear tree which brought little fruit to perfection on account of parasites. He experimented by picking and casting away a considerable proportion of the young fruit, and it was then noticed that the remainder went on to attain large size and to ripen. In both of these instances the disease was local, parasitic, but the trees were better able to resist the parasites because better nourished. Illustrations might be multiplied indefinitely, showing the resisting power of health over disease. Yet the principle seemed to be little applied by doctors in the treatment of the diseases of the skin. There was a very general exception, however, in favor of one drug in constitutional treatment, namely, arsenic. It would surprise many if he were to state to what extent this agent was administered by general practitioners in skin diseases, and yet it was used little by dermatologists, because it was seldom indicated.

The proper treatment of the diseases of the skin required the widest knowledge of general medicine. The author pointed out some aspects of the question as they had presented themselves to him in daily practice. Out of over ten thousand cases of diseases of the skin, Dr. Bulkley had found that six thousand required more or less general treatment in addition to local treatment. The remaining two-fifths belonged to new growths, parasitic diseases, etc., which required only local treatment.

The general conditions associated with the skin diseases and giving indications for treatment were connected with certain organs: 1, The digestive organs; 2, the liver; 3, the kidneys; 4, the nerves; 5, the circulation; 6, the respiratory system; 7, the sexual

system; 8, such general conditions as anæmia, gout, rheumatism, syphilis, malaria.

Perhaps the examples of closest connection with the digestive system were urticaria and acne, as shown by the results of treatment directed to the digestive tract. The author also named eczema, pruritus, and falling of the hair. Primary atonic or fermentative indigestion was not uncommon, but not so frequent as secondary or intestinal indigestion. The condition of the tongue was a valuable guide. Constipation was frequently present, although it might not be recognized by the patient. The bowel might be distended with waste matter, even though a movement took place every day. Liver disturbance played an important part in skin diseases. The value of nitric acid and calomel need only be recalled to appreciate this point.

Careful investigation of the renal function should never be neglected. Functional disturbances were more frequent than organic lesions. There might be transient albuminuria or glycosuria. The urea was a very important element, and must be considered in connection with the daily quantity of urine. Many patients suffering from skin affections showed insufficient kidney secretion. Haig and others had pointed out the important relation existing between the uric acid and various affections, the truth of which could be accepted without admitting all of their claims.

The condition of the skin itself, independent of the lesion in question, was to be considered—its harshness, its dryness, tendency to perspiration, to eruption. The amount of subcutaneous fat, the gain or loss of weight must not be overlooked.

In speaking of the nervous system, the author said it would often be found impossible to effect a permanent cure of skin affections without a sufficient amount of refreshing sleep. Sleeplessness was often connected with poor assimilation and disturbances of the circulatory system. Headache was very common in cases of skin affections, and neurasthenia or general nervous debility was often met with, and must be overcome as far as possible in order to obtain best results.

The part played by the circulatory system became evident from the value of digitalis or aconite and related drugs in certain cases. Palpitation, and flushing of the head and extremities, as well as cold and clammy hands and feet, were associated symptoms which required attention.

The respiratory system deserved special attention in connection with tuberculosis, lupus, etc. Among the associated diseases of the respiratory system were asthma, bronchitis, affections of the upper respiratory tract. Some of these alternated with skin affections, like eczema and acne. One should heed the condition of the breath.

A striking illustration of the relation of skin affections to the sexual system was seen in acne, which was so frequent at the age of puberty. A further illustration was the increased eruption at the menstrual epoch. Then there was gestation herpes, which disappeared with emptying of the uterus. Leucorrhœa acted directly when it produced pruritus or an eruption of the vulvæ, and indirectly by causing anæmia. Masturbation might be the cause of acne.

Finally, Dr. Bulkley mentioned the frequency of the conditions or diseases found in the eighth class as aggravating or causing skin affections—anæmia, gout, rheumatism, syphilis, etc. The uric-acid state, or lithæmia, was shown to have a probable relation to rheumatism by the benefit derived from salicylate of sodium, and with that benefit there was a happy effect upon the associated skin affection. Syphilis was recognized as a cause of nearly ten per cent. of all cases of skin diseases appearing at clinics. Modern treatment of this disease had largely diminished its ravages when present as a lesion of the skin. Regarding malaria, it was unquestionably true that certain cases of urticaria yielded best to quinine. Besides, malaria produced anæmia.

The author hoped he had shown the error of relying too much upon local remedies, and the necessity for the dermatologist as well as for all other specialists to be well informed in general medicine if they would succeed in the highest degree.

Dr. Louis A. Duhring, of Philadelphia, present by invitation, said he had become convinced more and more each year and each decade of the practical value of the principles enunciated in the paper. No doubt all present could give interesting clinical testimony, but the breadth of the subject necessitated the treatment of it in a general way. He was quite in accord with what had been said regarding the various systems and the part they took in diseases of the skin. The nervous system in particular had always impressed him as being a very potent factor in the production of the varied lesions of the skin. The literature of the past twenty years contained a vast amount of clinical material demonstrating this. In some instances the skin disease depended directly, in others indirectly or reflexly, upon the condition of the nervous system for its origin. An example was that of a girl of twenty-five years, who burned her wrist: the wound healed in two or three weeks, but subsequently a bullous and vesicular eruption appeared, which would not heal. In the course of two or three years marked trophic changes took place, and pains extended up the arm. The other arm became similarly affected, and a gangrenous condition developed. His efforts and those of his colleagues were without avail. Finally it occurred to him that the rest treatment might be tried; a friend took her into his institution, and after about two months she was well, except for occasional pains. Thus what had been considered a hopeless case was cured by rest and nutrition, without the aid of local treatment.

The author had spoken of the circulatory system, but had said little or nothing about the condition of the circulating fluid. When he was a student, blood diseases were spoken of only to show that there was nothing in them. But we had learned the last five years or more that there was a great deal in the blood, and there was still a great deal more to learn. He had in mind more particularly the toxæmias. These took a very important part in cutaneous pathology, particularly in erythema multiforme — an affection which he felt convinced depended upon a general, not upon a local condition. Then the list of known infectious diseases which gave rise to cutaneous lesions was growing rapidly. Pityriasis rosea, which was often mistaken for syphilis, belonged, he thought, to the diseases which had a general cause. A man was brought to him with lesions of the skin which had been regarded as leprosy, but Dr. Duhring expressed the opinion that it was dependent upon some malignant disease, although none was apparent. The patient died after three or four months, and autopsy revealed malignant disease of the pancreas and adjacent structures. Here the skin (of the upper extremities) was first to give a hint of hidden malignant disease of internal organs. Again, a physician had the scaly eruption of psoriasis, which resisted all treatment, and finally he became bedridden. He was told to take a two weeks' ocean voyage, but without any expectation of benefit; yet it resulted in disappearance of the eruption and placing him on his feet in two weeks' time. This without any medicine.

Dr. A. Jacobi mentioned the frequency of erythema in intestinal disturbances. Auto-infection in children and adults, with low fever sometimes extending over weeks, was often accompanied by erythema. Irrita-

tions of the sexual organs in females had long been known to be a cause of cutaneous eruptions. It had been stated by Lawson Tait that seven per cent. of laparotomies had been accompanied by cutaneous eruptions. There was only one way of curing eczema of the vulva in diabetes, namely, to cure the diabetes or put the vulva beyond the reach of the urine. In hysterical conditions we frequently found the skin dry, the hair dry and fragile, a change in the perspiration. Here we found skin eruptions; likewise in chlorosis, and connected with menstruation. Pregnancy often developed chloasma. Comedones, which appeared during puberty, were attributed by Dr. Jacobi rather to a bad habit which was common at this age, namely, masturbation.

Dr. Edward B. Bronson thought it should go without saying that the specialist must also be a doctor. In approaching skin diseases we must look for the principal etiological factor. From his point of view the cases could be divided under three heads: 1, Those in which the cause was reflex from some interior organ; 2, those which depended upon some malnutrition or inherent debility; 3, those which depended upon some external cause, like insect bites, etc. It seemed to Dr. Bronson that most importance attached to the local treatment of the disease. Even in cases falling under the first head, diseases which were symptomatic or dependent upon some general derangement, the removal of the latter was not sufficient to effect a cure of the skin lesion after this had become chronic, but local measures were also demanded. In rosacea the condition of the face might remain after the stomach irritation had been cured. Irritation of the sexual organs had been charged with the causation of acne at the period of puberty. But there were certain trophic changes going on at that period, certain alterations in the anatomy of the parts, which had much to do with the case. This was the period when the corneal structures of the body were growing rapidly. Comedones were not simply sebum; they contained a multitude of vegetable parasites, etc. They had not to do with dyspepsia or bad habits, but were due to the irritation of a foreign body, whose influence might extend to the production of pus—the pustular form of acne. In psoriasis, who would stop to give quinine or internal remedies? Local treatment was demanded. In the vast majority of cases chrysarobin produced immediate temporary benefit.

Dr. W. H. Draper said he had been much interested in the diseases of the skin the past twenty years. It was to their study that we were indebted for many facts in pathology and therapeutics. Some years ago, when he had lectured upon skin diseases, he would frequently say to students that he thought it not improbable that some day we would find many diseases, then regarded as constitutional or as depending upon known causes, to depend upon some particular poison. This fact had come to be demonstrated. Indeed, the whole pathology of septic diseases was a parasitic pathology. Many diseases treated by laryngologists, ophthalmologists, and other specialists were now admitted by them to be correlated with internal morbid conditions. An aurist had recently told him that many cases which he formerly treated locally he now found much more easy to control by attention to the general health. Most doctors, he believed, had rather a narrow conception of the cutaneous integument. From a broad point of view it should embrace the mucous integument, and he had found it most interesting to observe the analogy between affections of the mucous membrane and affections of the skin. In relation to some constitutional diseases this analogy was of vast importance. Dr. Bulkley had spoken of the relation of affections of the bronchial mucous tract to skin affections. Dr. Draper would extend it to the intestinal mucous tract, whose affections not infrequently alternated with those of the skin. This was observed, for example, in gout. In gouty families there was great vulnerability of both cutaneous and mucous integuments. He was not sure that many milder forms of cutaneous lesions were not dependent upon the gouty or lithæmic diathesis. Regarding the statement that acne was dependent upon masturbation, he thought it was hardly fair to many young people. He was more inclined to agree with Dr. Bronson, that it was due to a physiological change which occurred about the age of puberty. One author had spoken of acne as occurring at the age of chastity. Dr. Draper thought there was not much danger of exaggerating the constitutional element to the exclusion of the local in the treatment of skin diseases. While both should receive their due amount of attention, there were many cases in which, if he were limited either to local or to constitutional treatment, he would choose the latter. Eczema in children was likely to be connected with too free indulgence in sugar and starchy foods—the carbohydrates. The influence of the nervous system upon the cutaneous surface was seen in herpes zoster and in the glossy skin in neuritis.

Dr. R. W. Wilcox thought we had come to the point where it was necessary to separate cases of disease of the skin into two classes—those which indicated a disorder of the skin itself, and those which were symptomatic of internal derangement. While it was true that dermatologists had probably overlooked general causes, it was equally true that internalists had often overlooked local causes. The two should come together, that we might arrive at a clearer conception of how far internal or general treatment on the one hand and of local treatment on the other was indicated. The influence of serum treatment pointed to a general condition in the etiology of erythema and urticaria in many instances, and he thought it would come to be shown that these were usually symptomatic of internal rather than of local disease. No doubt all had observed eczema alternate with gout and lithæmia. Its relation to the urinary function had properly been pointed out by the author. Dr. Wilcox thought it was necessary in some cases of skin disease to place chief dependence upon internal treatment, in others upon local treatment, in still others upon a combination of the two.

Dr. Bulkley said he was glad Dr. Bronson had made a strong contention for local pathology. But a reference to the figures given in his paper would show that he (Dr. Bulkley) had not overlooked the fact that in many cases the cause and the treatment were chiefly or entirely local. On the other hand, it had been his purpose to direct attention to that other large class of cases in which general treatment was demanded. In this he had been ably supported by other speakers. Regarding infantile eczema, local treatment alone, unaided by attention to the internal causes, would utimately result only in more frequent and more rebellious attacks. He also disagreed with Dr. Bronson regarding psoriasis; chrysarobin gave only temporary relief, but the disease was not incurable, for in many cases continued attention to the diet and general health effected permanent cures.

The Health Board of the Greater New York.—Dr. A. Jacobi, who at the last meeting had moved to lay the report of the committee on the subject of the health department in the charter of the Greater New York on the table, now moved to take it up and adopt it, together with a few additions which he had suggested at the former meeting. The report of the committee and of the two sections of the proposed charter which Dr. Jacobi would have stricken out are to be found in the Medical Record, March 27th, pp. 456

and 457. Briefly stated, the report of the committee looked to the abolition of the clause disqualifying a physician from becoming president of the board of health, and also to doing away with the office of coroner.

In the discussion which followed at the present meeting no opposition was offered to these recommendations, but Drs. Bryant and Janeway thought it would weaken the board of health in times of emergency to strike out sections 1,248 and 1,249 in their entirety.

Dr. Jacobi, at the close of the discussion, changed his motion to include the adoption of the report of the committee with the following additions: In section 1,248 strike out simply the time limit named for reporting contagious and infectious diseases when demanded, which was three hours. This time limit, he said, was an impossibility. Further, in section 1,249 strike out the following: "It shall be the duty of each visiting physician to make an immediate report to the department of health of the name of every practising physician by whom he shall have reason to believe the provisions of said section have been violated; and if such physician shall neglect or refuse to perform his duty, the department shall order him to be suspended from any office he may hold, and he shall, moreover, be liable to such further penalty and to such prosecution for his violation of this law and of his duty as the board of health shall determine."

Dr. Bryant said he agreed with Dr. Jacobi in his objection to making physicians spies on their fellow-practitioners, as this section would do.

Dr. Jacobi's motion to adopt was carried.

SECTION ON GENERAL MEDICINE.

Stated Meeting, March 16, 1897.

Louis Faugères Bishop, M.D., Chairman.

Case of Chronic Gout with Remarkable Deformities.—Dr. Charles E. Nammack presented a man forty-seven years of age, a sufferer from gout since the age of twenty-one. Since that time he had had repeated acute attacks, and deposits of urates had disabled his hands and formed large knotty tumors around the joints of the hands and feet and in other localities. Attention was called to the fact that the deposits in this disease were about the joints, and in the tendons and sheaths, whereas in arthritis deformans there might be even greater deformity, but the enlargements were true exostoses on the articular surfaces. Skiagraphs of the case presented had been taken, and showed absence of destruction of the intra-articular cartilage and ends of the bones, the tumors being more to one side, or between the joints. The theory of a gouty origin of Dupuytren contraction, believed in by some, had been opposed in a paper by Dr. Abbe, who attributed it to trauma in the end nerves reflected to the central nervous system and thence to the terminals. Dr. Nammack presented a man with Dupuytren contraction in contrast with the case of gouty deformity. The man was a saddler, and the traumatism could be attributed to the use of the needle.

Improved Stethoscope and Plessimeter. — Dr. Knopf exhibited and described the instruments. To appear in the Medical Record.

Fluorography for Determining the Position, Size, and Movements of the Heart, with Demonstrations. —Dr. Thomas E. Satterthwaite read the paper and made the demonstrations (see page 508).

Dr. Reynold W. Wilcox was asked to open the discussion. The work of Dr. Satterthwaite, he said, was not only opportune, but important. For the past three or four years we had read articles from our British cousins on the effect of resistant exercises and baths as carried out at Bad Nauheim, the results of cardiac contraction being shown by drawings which set at defiance all conceived notions of cardiac anatomy and of the reliability of percussion and auscultation. If we could, as he believed we could, add sight by this fluorographic method to auscultation and percussion, we would be able to compare landmarks and arrive at a satisfactory opinion of what went on in the heart under the treatment named, or any other kind of treatment. The facts which Dr. Satterthwaite had brought out very strongly had apparently escaped all other observers. McEntyre had made the bold statement before the British Medical Association, last July, that the outline of the heart shown by the *x*-ray was the more accurate the farther the screen was removed from the patient. In Dr. Williams' experiments, published last October, the patient lay on a cot, the tube distant about eighteen inches, and the outline of the heart as determined by the Roentgen ray was very much larger than that determined by percussion. Dr. Satterthwaite had, so far as he could judge, gone farther and given us an absolute means of outlining the heart by sight. This was accomplished by moving the tube successively to different angles of the heart as the shadow-line was drawn by pencil on paper over the fluoroscopic screen. The accuracy of the method was shown by its close approach to the outline drawn on careful percussion. The only difference in the outline as determined by the two methods was at the apex, and that could be accounted for partly by the fact that in percussing the heart one was likely to be guided to some extent with regard to the position of the apex by its beat, and partly by other considerations. The difference in the density of the heart in diastole and systole, owing to the presence or absence of blood within the muscle, as pointed out by Benedict, showed that in systole the cavities were not completely emptied, and this fact, made apparent by the *x*-ray, was, he believed, in accord with recent physiology.

The experiments had also brought out one or two incidental facts. One was that if there should be considerable tuberculous deposit in the lung near the heart it might interfere with the accuracy of the cardiac outline. On the other hand in emphysema of the lung, which made it very difficult to outline the heart by percussion, the *x*-ray showed the heart and its limitations very distinctly.

This demonstration could be welcomed as a real advance, not only as an aid to hearing and touch, but as confirming and extending the knowledge of anatomy and physiology, and convincing those whose hearing and touch were not so acute or well trained as the specialist's.

Dr. William H. Porter fully agreed with Dr. Wilcox, that they were under great obligations to Dr. Satterthwaite for having brought the fluorographic method to a more perfect position than it had ever before occupied. With the first speaker he had witnessed these demonstrations in private, and had observed the almost absolute correspondence of the two outlines of the heart, one drawn by percussion, the other by the fluorograph in the manner described. One of the most interesting things noted by him during the demonstration was the clear outline between the diaphragm and heart and the movements of the former with each respiration. As the diaphragm descended, it seemed to leave a vacuum between itself and the heart. In auscultatory percussion it was somewhat difficult to outline that portion of the heart, and also to determine at one point what was heart dulness and what was liver dulness. By the method demonstrated by Dr. Satterthwaite one could certainly map out that portion of

the heart with greater certainty. How practical the methods would become in general practice, time alone could determine. He thought mediastinal tumors, especially aneurisms, would be shown.

Dr. S. S. Burt thought the method was likely to be of marked value in determining the dividing line between the heart and liver, which was apt to rest in doubt under percussion: also that the method was likely to be of value in cases of aneurismal dilatation of the aorta.

Dr. Charles E. Quimby remarked that the outline of the heart was shown very clearly during this demonstration, and corroborated what had previously been determined by percussion.

Dr. Satterthwaite said in closing that this study of the heart as seen by this method had been to him a very interesting one. It had taken him about a month to make the various experiments. He also thought by this method it would be possible to get a view of the heart from the side. Heretofore it had been seen only from the front or back. As Dr. Wilcox had suggested, he believed the method would give new facts in physiology and undoubtedly would correct many of the cuts which now appear in books on physical diagnosis. This was especially true of cuts representing the movements of the heart; for they were not the same under the fluoroscope as in book representations. The point mentioned by Dr. Porter, with regard to the outline of the diaphragm and space between it and the heart under inspiration, became very striking during deep inspiration. While the demonstration of the heart by this method appeared somewhat tedious, he did not think it would require more time than was commonly taken for examination of the urine in a case of Bright's disease. It required only about fifteen minutes with good apparatus, but with improved methods which he had in view there would be a further reduction in time.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MEDICAL QUESTIONS IN PARLIAMENT—PERITONEAL INFECTIONS AND PROTECTIVE SERUMS—RETROPERITONEAL TUMORS—EXCISION OF KNEE BY A NEW PROCEDURE—INTESTINAL NEUROSES—OLIVER PEMBERTON'S WIDOW—DIPHTHERIA.

London, March 19, 1897.

Some interesting questions have come before the house of commons, *e.g.*, the suppression of rabies, as to which lovers of dogs maintain an unreasonable attitude; the London water supply, which is to have a royal commission, and so the several bills before the house were rejected; vivisection, toward which the anti's display their opposition in the most vexatious way, circulating utterly ridiculous statements of a libellous nature; the alleged increase of lunacy, the report of the inquiry on this subject being laid on the table; the metropolitan pauper children, concerning which we are likely to hear much in consequence of the decision to make separate provision for special classes of such children.

At the last meeting of the Royal Medical and Chirurgical Society, Mr. Herbert Durham read a paper on the clinical bearing of some experiments on peritoneal infections. You will remember that Isaeff has shown that considerable resistance to microbes is obtained by inducing leucocytosis. If sterilized water, or serum, or broth, be injected into the peritoneal cavity, an animal can the next day receive with impunity fifteen times the fatal dose of a culture of cholera vibrios. Following this line of investigation, Mr. Durham has protected guinea-pigs from several microbes, and attributes the protection (1) to increased bactericidal power of the peritoneal fluid after injection; (2) to the presence of a large number of active phagocytes, which are not seen in normal peritoneal fluid. He suggested accordingly that a person might be protected in a similar way prior to operations for perityphlitis, tubal abscess, etc. In most cases the active organisms are streptococci, and he would, therefore, propose an injection of antistreptococcic serum the day before opening the abdominal cavity. There may be no organisms and no lymph in the peritoneal fluid in subjects that die rapidly, but in the lymph spaces of the omentum and other membranes organisms can be found. The injection proposed would increase the general resistance of the tissues, as well as afford immunity from streptococcal invasion. Mr. Durham insisted on thoroughly cleansing the omentum and the space between the liver and diaphragm, where the organisms are most abundant.

Mr. Lockwood agreed that there is a great difference according to the organisms present, and that streptococci were most dangerous; but as they are in the substance of the membranes and not on the surface they cannot be dislodged, and if the tissues can be prepared to resist them it would be a most valuable expedient.

Mr. Harrison Cripps remarked that when fœtid pus escaped into the peritoneum the more severe forms of peritonitis were rare, and perhaps the existence of pus in contact with the membrane protected it. He doubted if washing out the space between the liver and diaphragm could be managed, as it was so high up and the surfaces were in close contact.

Mr. Marmaduke Shield read an account of the removal of a large solid tumor from the retroperitoneal space. The patient was a woman of fifty-two. Many laminæ of condensed fibrous tissue had to be stripped off the tumor, which seemed to be lying in front of the spine, but was easily separated from the aorta and vena cava. There were numerous adhesions containing large vessels. The tumor was a fibro-myoma. It was difficult to determine the precise origin. Mr. Eve thought it originated in unstriped muscular tissue. Mr. Lockwood remarked that sarcomata in this position were usually encapsuled, and their removal was easy unless they were very soft. Mr. Cripps thought many grew from the broad ligament, and were not strictly retroperitoneal. This tumor was, perhaps, originally a detached fibroid. In such cases there were often many adhesions, and it was best to follow Sir Spencer Wells' plan of extending the incision upward, so as to get into the peritoneal cavity higher up.

At the Medical Society meeting Mr. Lockwood read a paper in which he passed in review the various operations for excision of the knee, and gave a detailed account of a new procedure, which he called osteoplastic excision, and which has been successful when other methods of treatment have failed. The new method was favorably received by the surgeons present and the best plan of maintaining fixation after the operation was dwelt upon. Mr. C. Dent then read a paper on intestinal neuroses, and detailed some cases showing the difficulty of distinguishing between them and those in which the symptoms pointed to some surgical affection which would justify an exploratory operation, but he did not approve of laparotomy in cases believed to be due to neurosis merely because an operation had sometimes given relief, although no obvious lesion had been found.

Mr. Shield mentioned a case in which the classical symptoms of renal calculus were present, but on operation no trace of stone could be found, though the symptoms disappeared after the operation. Mr. Lockwood thought that surgeons would not get to the bottom of such cases until they more generally recorded those in

which they found nothing on opening the abdomen, and remarked that adhesions pointing to past disease were sometimes met with. Mr. Harrison (president) referred to the intense distress of some patients with varicocele, which suggested some disturbance beyond that which was apparent.

The widow of Oliver Pemberton, whose death I announced in my last letter, died within a week of her husband's decease.

The deaths from diphtheria rose again last week to fifty-three, being twenty-one in excess of the average for the last ten years.

OUR PARIS LETTER.

(From our Special Correspondent.)

EPIDEMIC OF PHOSPHORIC NECROSIS—PROPHYLACTIC MEASURES AGAINST—BOOKS AND THE ACADEMY OF MEDICINE—THE BUBONIC PEST AND IMMUNITY BY HYPONITRIC VAPORS—PNEUMONIA AND THE BACILLUS OF FRIEDLANDER, ETC.

PARIS, March 18, 1897.

THE question of substituting for the harmful white phosphorus the red and less necrotic product was referred to some months ago. It is again being agitated. It is not, however, necessary to dwell upon the ravages that the fabrication of matches causes among workers in their manufacture. The time has indeed come to do something in this matter, as phosphoric necrosis is now little short of epidemic in some parts of France. The minister of finances in consequence asked the Academy of Medicine not long since to give him its opinion upon this question of hygiene, in order to arrive, if possible, at a practical solution of it. Propositions of the following kind are being considered: Dr. Vallin, speaking on behalf of the commission appointed for the purpose, wisely concludes that radical measures are necessary. He advocates strongly the abolition of white phosphorus in the manufacture of matches, and the substitution in its place of red phosphorus, of which the harmfulness is infinitely less.

A remarkable change of opinion on this subject has been shown by Dr. Magitot, who not long since was an avowed enemy of white phosphorus, the use of which he advocates to-day. Dr. Magitot, we are informed, has taken up the idea that considerable expense would be incurred in substituting the one form of phosphorus for the other, and this to industrial detriment. He is of opinion that the thorough and constant ventilation of manufactories, with a strict choice of only vigorous workmen having healthy teeth, constitute the two most sufficient and necessary measures to be taken in the premises.

Doubtless these are extremely valuable suggestions, as we all know that dental caries, bad and decaying teeth in general, are the porte d'entrée of phosphoric necrosis. But neither Dr. Vallin nor Dr. Roussel considers these measures, which after all are only half measures, sufficient. Such rigorous ventilation as is proposed is possible only during the winter months in the south of France or Algiers, and it is in the northern provinces that the disease is most prevalent. The hygiene of the mouth is the most efficacious prophylactic means against the development of phosphoric necrosis. This, however, is very difficult to accomplish. It is often difficult even among the better classes, and how much more so would it be among workmen and workwomen?

As regards the substitution of a less harmful form of phosphorus for that now in use, something might be accomplished, but only something, because phosphorus in any form would produce the same pathological conditions, varying of course as to the symptoms, the number of people affected, etc., in accordance with the toxic power of the preparation employed. The individual resistance must also be taken into account. We would also suggest that those at the head of the large match factories first see that their employees have sound teeth, then that they brush them night and morning, and rinse the mouth several times a day with an antiseptic soluiton of thyme, carbolic acid, and borated water. The tooth powder prescribed should be simply camphorated chalk, pure.

The Academy of Medicine has just elected Dr. Napias in the section of hygiene. Dr. Napias is inspector general of beneficent establishments at the ministry of the interior. Although comparatively a young man, he is thoroughly up in the science of hygiene, and is best known by his labors in the department of public health and organization. Dr. Albert Robin has just presented to the academy two new volumes of his "Dictionnaire de Thérapeutique," and Professor Debove the last volume of his "Manuel de Médecine." Prof. Charles Richet has recently given out a monograph for his "Dictionnaire de Physiologie." This likewise was presented to the Academy of Medicine. Indeed, the library of the academy is constantly receiving valuable contributions from its members. The most important, however, is Professor Dieulafoy's great book on internal medicine, in four volumes. This is a work of such importance and scope as to merit more extensive notice and review, which we shall undertake in our next letter. Professor Richet's monograph is most interesting and is written in his clear incisive style. The article "Cerveau" (brain) is an epitome of the subject from antiquity down to the present day. All the philosophers, the savants of all times and of all countries who have written on the brain find their places in this erudite and deeply instructive history of the human mind, from those who first taught and wrote on the subject—Aleméon, Herophilus, Erasistratus, down to Ramon y Caja., and last but by no means least, the eminent author himself.

Speaking of the bubonic pest that has been claiming to such an extent the attention of the scientific world lately, a recent letter from Bombay to the *Semaine Médicale* calls attention to some singular facts. It seems that the "indigenes" employed at "la monnaie," or the mint, are not affected with plague, although these workmen live in infected quarters. The reason for this immunity is found in the fact of their breathing an atmosphere impregnated with the vapors of hyponitric acid. The plague, although diminishing in Bombay, shows a tendency to spread to the northward. At Mandri, one of the quarters first contaminated, the number of cases every week is actually small and the number of deaths almost nil. It is well known that epidemics of plague in the human being are preceeded by epidemics of the disease among the rats and mice, who die in great numbers. This, however, was not the case at Poonah, although it did immediately precede the appearance of the epidemics both at Bombay and at Hong-Kong.

Several cases have lately been reported of purulent pleurisy complicated with pneumonia due to the bacillus of Friedlander. Professor Rendu, for instance, has had two cases, one of which terminated fatally, the other recovering only after numerous complications. Professor Rendu says regarding them: "The impression left me of these two cases is that pneumonia with the bacillus of Friedlander is of an especially grave prognosis."

THE CRIME OF ABORTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: There is a crime of only too common occurrence to-day, reference to which is seldom made by ministers, who must be unacquainted with the actual condition

of affairs, for, if they were not, I believe more of them would raise their voices against this evil.

Fellow-practitioners, look over your list of patients. Note the number of families having less than three children, some having only one. Why is it, may I ask, that the American family, which formerly numbered eight or ten, now numbers from one to four? Is it because God has made the genital tract of our society belles different from that of our dear old grandmothers, or that the passion for sexual intercourse is on the decline? We all know such is not the case. Then what is it? I answer, in the diabolical practices of many of the married people of to-day. Crimes of onanism, preventing conception, and abortion are so common that many women of to-day take great pleasure in teaching others the various methods of practising these evils. I know of one woman who was so boastful that she told a young man, who went to see her about performing an abortion upon a girl he had gotten pregnant, that she had had one hundred successful abortions!

Think of it—one hundred lives taken right in a city having a dozen churches, having only twenty thousand souls! Yet this woman will continue with her diabolical work, for a physician cannot betray a professional secret.

Many young girls of to-day are anxious to enter the married state, and yet do not wish to take responsibilities of that state. Child bearing is not the fashion. She must not think of it! Many mothers teach their daughters these diabolical practices.

The sexual instinct was given man for no other purpose than the reproduction of his species, and to use it for any other purpose, or to prevent conception taking place, is evil and an insult to divine providence.

"Evil is the turning of an act from the course in which it was intended," or, as St. Augustine says, to leave the path of truth. If preventing conception, onanism, and abortion are not turning an act from the course in which it was intended, I am very much mistaken in what evil is.

Many try to apologize for taking medicine to bring them "round," by saying there is no life in a conception of only a week's or ten days' duration. O misguided conscience, how easy thou art to bend! Can anything be more false? What is life? Life, says Meagher, is an active principle which is in each living being, and is the source of all its internal and external phenomena, acts, and movements. Let us hear St. Thomas; he says: "A being lives when it moves itself."

Before going any further, let us define the soul. The soul, says a learned scholastic, is the substantial form of a being. The moment conception takes place, the soul and that vital force called life must be instilled into the ovum. Life must be present, for if it were not development could not take place. The soul must be there, for if it were not this impregnated ovum would never develop into a living being.

Take the soul, or vital force, life, away from an adult, and what is the result? Death. Do the same with an impregnated ovum: what is the result? Death. If it is murder to do the former, is it not murder to do the latter? Do you not accomplish the same end in either case?

A European theologian has wisely said: "The younger the child, the greater the crime." Is this not true? If you attempt to take the life of a man, he has at least some chance of saving himself by running away, crying for assistance, or by the protection which the law affords him. But not so with an impregnated ovum; here are a life and a soul at the mercy of a woman whom the law can hardly reach. I believe if physicians of to-day, who are spending so much time trying to educate people in preventing disease, would teach them the grievousness of interfering with or preventing conception, they would do a great deal for God and their country and save many an innocent babe its life.

H. P. Beirne, M.D.,
Professor of Natural Science, Corpus Christi Lyceum.
Galesburg, Ill.

DISINFECTION OF THE HANDS.

To the Editor of the Medical Record.

Sir: I beg the privilege of your space to supplement Dr. Weir's paper on "Disinfection of the Hands," in your latest issue, April 3d, by a brief statement concerning the clinical use that has been made of the mixture of chloride of lime and carbonate of sodium, which gave the largest percentage of successes in his bacteriological tests.

The use of the mixture was suggested, as Dr. Weir says, by Mr. Rauschenberg, the apothecary of the New York Hospital, but the suggestion was made to me, not to Dr. Weir, and was adopted either in the autumn of 1892 or the summer of 1893. Since that time the method has been in constant use in the first division of the New York Hospital by Dr. Hartley and myself, and in the second division by Dr. Murray, and also in the Hudson Street Hospital, and was mentioned as in such use in a paper read before the Surgical Society a year ago and published in the *Annals of Surgery* in May, 1896. Dr. Weir made no use of it before December, 1896.

I am surprised that in a paper containing so many references to foreign work on other points, such a patent reference to a fact bearing so directly upon the main subject of the paper should have been omitted. It would have gone far to forestall Dr. Bull's and Dr. McBurney's criticism of the lack of clinical evidence, and would have been a fitting acknowledgment of indebtedness to others for faith and works which gave Dr. Weir his knowledge of the method and kept it before his eyes for three years, and without which his laboratory tests would probably not have been made, or, if made, would have seemed to most only an addition of doubtful value to all those other similar tests, which Dr. Bull characterized as "bewildering." Furthermore, if opinion long current in the hospital is well founded, study of clinical data would have furnished evidence so convincing that laboratory tests would have seemed superfluous.

Lewis A. Stimson, M.D.
New York, April 5, 1897.

Hemorrhage from the Bowels in Typhoid Fever.—Dr. William Osler (*Maryland Medical Journal*, November 14, 1896) writes the following: "Bleeding of moderate amount may occur and cause no special anxiety, except, perhaps, the unavoidable apprehension lest the bleeding should recur in a more grave form. Hemorrhage is one of the most dreaded accidents of the disease, and justly so, since it may occur when everything has gone along smoothly and the patient appears to be improving in every way. In two hundred and thirty-nine cases of typhoid fever treated in six years in the Johns Hopkins Hospital, there were twenty cases of hemorrhage; three patients died from loss of blood, and three from perforation after bleeding had ceased. [Cases are quoted showing history, etc., of hemorrhage.] The treatment pursued is as follows: The lead-and-opium pill by the mouth and small doses of morphine hypodermically. Normal salt solution is injected when there is much loss of blood, and favorable results follow its use in most desperate cases. A fatal result may follow in typhoid fever without blood appearing externally, so we must be on our guard. There are cases where hemorrhage recurs at intervals."

Therapeutic Hints.

Dyspepsia Accompanied by Acne. — Dr. Mitour (*Revue de Thérap.*, December 15, 1896) recommends for dyspepsia accompanied by acne, light meals frequently repeated. The food should be well masticated, and of a kind easily digested. Bread, spiced meats, preserved fish, pastry, butter, and fatty foods should be avoided. Alcohol and milk are also injurious. Water is the best drink and should be taken sparingly with meals. Medical treatment has three objects. (1) To stimulate the secretion of hydrochloric acid, there should be given before meals bicarbonate of sodium with sulphate of sodium and of potassium in small doses, or ipecac, or condurango. (2) To stimulate muscular action of the stomach, the tincture of nux vomica may be given after meals. (3) To prevent fermentation, naphthol, benzol, beta-naphthol, or salicylate of bismuth are indicated. Sulphate of sodium and calomel are recommended for constipation with intestinal inflammation. Hydropathy with abdominal massage, gastric lavage, and electricity have given excellent results in certain cases.

—*Atlanta Clinic.*

Gastric and Intestinal Antisepsis.—Dr. Patterson (*Canadian Practitioner*, December, 1896) says that the first indication in carrying out disinfection of the bowel is to empty it, and for this purpose purgatives are pre-eminent. Calomel fulfils the requirements of an ideal intestinal antiseptic. It induces free movements of the bowels both by its local action and by excitation of the intestinal ganglia, while the risk of its affecting the mucous membranes is but small. During its passage through the intestines it is converted into the perchloride, which restrains excessive intestinal decomposition. This change takes place slowly and gradually in children, as in the adult. Wassiloeff observes that calomel is without action on the digestive ferment, and consequently we have in calomel a substance whose mode of action is simply and easily controlled.

Gout.—Dr. Hans Froelich (*Journal of the American Medical Association*, January 30th) thinks that local treatment is the most effective. We are accustomed to regard a surgical treatment of the local precipitation of urates, the tophi, as almost a sacrilege. However, they are foreign bodies, and all foreign bodies, if accessible, ought to be removed. There is much talked and written about dissolving these urates with lithium salts, piperazin, and, of late, lysidri. They work nicely in the reagent tube with water, but as soon as we take urine the dissolving effect stops. Dr. Froelich is unable to say how they work in plasma. If they are locally injected in a solution strong enough to take effect, the resulting chemic process causes a painful inflammation which lasts almost two days. The only way to remove these tophi is by curetting under asepsis; it ought certainly be done in each case during the time no acute attack is apparent.

Neurasthenia.—Dr. John A. Hale warns us that in the treatment of this trouble he has found patients of both sexes easily affected by stimulants, and that often they feel a desire for such, and in our anxiety to benefit the patient we may be too careless and establish a condition far more serious than the disease itself. Use stimulants when necessary, but use them judiciously, and keep prominently in mind the one expressive word of warning: "Beware."

The Serum Reaction in Typhoid Fever and Experimental Cholera.—Drs. Johnston and McTaggart (*The Canada Lancet*, February, p. 307) draw the following conclusions from their observations on the reaction in typhoid fever and experimental cholera by the dried-blood method. (1) The use of dry-blood-serum diagnosis has given what appeared to be satisfactory results for diagnostic work. (2) An incomplete reaction was occasionally obtained as early as the end of the second day. (3) The complete reaction was rarely delayed beyond the fifth day. (4) Typhoid blood allowed to dry for sixty days still gave the typical reaction. This might permit of its application to medico-legal work. (5) In experimental cholera immunity, a typical reaction was obtained with dried blood. (6) The reaction may appear after a single dose of typhoid or cholera culture. (7) There is a possibility that the clumping of the typhoid bacilli may be utilized as a means of isolating them from cultures made from water, fæces, etc.

Umbilical Hernia Containing the Heart in a New-Born Infant.—Dr. Arndt (*Centralblatt für Gynäkologie*, 1896, No. 24) reports the case of a child apparently in good health when born. At the umbilicus there was a tumor of the size of an apple, contiguous with the cord. Through the walls of the tumor could be seen coils of the intestines, the liver, and the pulsating heart. Cœliotomy was performed seven hours after birth. In the hernial sac was found the heart, the deformed liver, the stomach, the ileum, and part of the colon The heart, which was not surrounded by pericardium, could not be replaced in the thorax, making the prognosis absolutely fatal.

Version with the Patient in the Prone Fosition.—Dr. Mesinger (*Centralblatt für Gynäkologie*, 1897, No. 23) advises this method, because the outlet of the pelvis is directed above, giving the operator much more room for the insertion of the hand. The operator's hand and arm are in the position of pronation, giving a better use of the muscles and tactile sense.

This posture widens and opens the vagina and uterus. The risk of bruising the soft parts is less, and the danger of tearing the uterus from the vagina and of air embolism is minimized.

Anæsthetics in Labor.—Dr. Alexander Ballantyne read a paper on this subject before the Edinburgh Clinical Society, November 11, 1896, which he concluded as follows: "(1) The simpler the mode of administration the better, but care and watchfulness are all-important; (2) the best diluent is air, which ought freely to be admitted; (3) persistently attend to the respiration; (4) in a normal labor give chloroform only during a pain until the head is on the perineum, when it may be given to full unconsciousness; (5) after the birth of the head discontinue its use." The president further maintained that "(1) we are always justified in giving chloroform in normal labor, and (2) we should always do so in severe labor and in all cases of operative interference; (3) that in all diseases of the heart, and in all diseased conditions of the blood-vessels, the careful administration of the drug is beneficial, and often necessary to save life; (4) that in general emphysema of the lungs the greatest care and watchfulness should be exercised in its exhibition, and that in conditions of great exhaustion and after great, rapid, and recent loss of blood, as in placenta prævia, extreme caution is necessary, and it may be ether should be substituted."

Catharsis for Pregnant and Lying-in Women.—Dr. Edward P. Davis read a paper, at the meeting of the American Gynecological Society, on "Intestinal Bacteria as a Source of Infection Complicating Obstetric Operations," and asked several therapeutists regarding the best purgative to secure an antiseptic condition of the intestine. Professor Han advised a minute dose of mercury, one-two-hundredth to one-one-hundred-and-twentieth of a grain of the bichloride of mercury, several times a day for a number of days, in conjunction with saline purgatives.

Resection for Artificial Anus Unnecessary.—Dr. Greig Smith has come to the conclusion that it is never necessary to resect for artificial anus. He has had many cases of fæcal fistula, and in nearly all has succeeded in bringing about closure by an external operation, without opening the perineum. For the resection of tumors it is vastly preferable to do the operation in two sittings; in such cases recovery always follows.

Acne.—Dr. Bardach thinks that the irritation of the sebaceous glands is brought about by the increase of solids in the blood. In these cases a quick cure is effected by increasing diuresis. For local treatment he suggests a soap containing about one and one-half per cent. of iodate and bromate of sodium.—*Derm. Zeitschr.*

Duration of Acute Gonorrhœa under Treatment.—Dr. H. M. Christian (*Therapeutical Gazette*, January 15th), after a careful study of statistics, draws the following conclusions: (1) That gonorrhœa is a much more prolonged and serious affection than it is usually considered to be by general practitioners of medicine and by the laity. (2) That in two-thirds of all cases uncomplicated the period of time necessary to obtain a complete cure is from six to ten weeks. (3) In that small proportion of cases in which the entire urethra does not become involved, the disease being confined entirely to the anterior urethra, we can, as a rule, expect complete recovery in about four weeks. (4) The necessity of impressing upon the profession in general the importance of making examinations of the urine before deciding that an attack of gonorrhœa is positively cured.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 3, 1897:

	Cases.	Deaths.
Tuberculosis	247	126
Typhoid fever	2	4
Scarlet fever	159	13
Cerebro-spinal meningitis	2	2
Measles	196	13
Diphtheria	204	30
Laryngeal diphtheria (croup)	6	0
Small-pox	6	0
Chicken-pox	36	0

Pyoctanate of Mercury is prepared by treating a solution of pyoctanin with a solution of bichloride of mercury in hydrochlorate of ammonium. A precipitate containing fifty-five per cent. of mercury is obtained, which may be employed in from one-half to one-per-cent. strength in favus and chronic gonorrhœa. It has also been used to replace iodoform and for severe burns. A gauze is also prepared by taking one hundred parts of unstarched gauze, and sixty of a solution containing one gram of sublimate and five grams of hydrochlorate of ammonium; after drying it is wet for the second time with a one-half per cent. of pyoctanin and again dried.—*La Méd. Mod.*, March 6th.

Cremation in England.—The report of the council of the Cremation Society of England for 1896 shows that one hundred and thirty-seven cremations were carried out at Woking during the year. There has been a steady increase in the number of cremations each year until 1896, but even in the latter year the number of cremations was greater than in any other previous year except 1895, when there were exactly one hundred and fifty. There are three other crematories in England and Scotland, at which sixty-five bodies were incinerated in 1896.

"Mental Impressions and Disease" is the title of a neat little brochure by William T. Belfield, published by the Chicago Literary Club. Its aim is to show that there is a value in the production of mental impressions for the cure of emotional diseases, and the author carries out his purpose in a most entertaining manner. His insight into the workings of a queen bee's mind makes it clear why his belief in a soul has survived a long residence in Chicago.

More Statistics in Favor of the Serum Treatment of Diphtheria.—Dr. Cuno (*Deutsche med. Woch.*, December 24, 1896) reports the results of two years' treatment of diphtheria with Behring's serum at a hospital in Frankfurt. There were four hundred and eighty-three cases in all, and the mortality fell from never less than thirty-seven per cent. in previous years to 10.5 per cent. of the total number, or 7.03 per cent. excluding the moribund cases. No local treatment whatever was used. It was found that with sufficient doses of No. 3 serum the false membranes rolled up at the edges, seemed to dry up, and were finally expelled without the need of bothering the patient with local applications. Heart weakness was combated with injections of alcohol and camphor, and abundant nourishment was given through a sound if necessary.

Naphthalan is the name of an establishment at Elizabethpol, Russia, in which petroleum is said to be successfully applied in the cure of gouty affections and rheumatism.

THE NERVES OF THE PERITONEUM (WITH SEVEN ORIGINAL DRAWINGS BY THE AUTHOR).

BY BYRON ROBINSON, B.S., M.D.,

CHICAGO.

THE nerves found in the peritoneum are:

1. Medullated nerves.
2. Non-medullated nerves.
3. Remak's nerve fibres.
4. The Vater-Pacinian corpuscle, and other forms of nerve endings and nerve bulbs.
5. Nerve cells (Fig. 1).

I speak of the method of preparation as one of the most important parts of this theme. I spent much time with the Ag. No. 3 method, but with uncertain, unsatisfactory results. Considerable time was spent with the osmic-acid process, with some good results, especially in demonstrating the fine, non-medullated, nucleated nerve fibres around the small artery or blood-vessel, but with some uncertainty. The method superior to all others of preparing and demonstrating the nerves of the peritoneum is by the use of gold chloride and acetic acid; I finally discarded all other methods. The beautiful clearing process of acetic acid is not likely to be forgotten, and the distinct borders and outlines that the gold chloride furnishes to the nerve fibres is likely to be cherished by the nerve searcher. However, gold-chloride specimens are somewhat uncertain and evanescent. The method which I finally adopted was that suggested by E. Cyon, in 1868. The stain is compounded and used as follows:

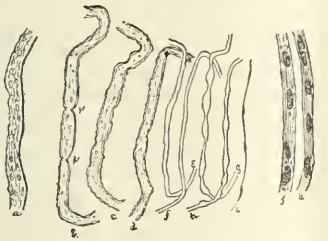

FIG. 1.—The individual nerves from the peritoneum of cat and rabbit as they appear under the microscope after treatment with acetic acid and gold chloride. *a*, A wide medullated nerve, with advanced coagulation, about 48 hours after death and preparation; *b*, a wide medullated nerve with two nodes of Ranvier at *r* and *r*—a recent and fresh preparation; *c*, a wide medullated nerve a few hours after death and preparation; *d*, a moderately wide medullated nerve shortly after death and preparation; *e*, a narrow medullated nerve showing no coagulation; *f*, a still narrower medullated nerve with the medulla not visible; *g*, a narrow medullated nerve with the medullary sheath forced into bead-like accumulations; *h*, a still narrower medullated nerve, also showing bead-like accumulations of myelin at varying distances from each other; *i*, fibrillated fusiform axis cylinder, non-medullated but nucleated; *j* and *k*, two fibres of Remak showing their nuclei in the neurilemma and fibrillated axis. By observing the nerve fibres of the peritoneum from recent preparations and from day to day up to 15 days, all kinds and phases of coagulation can be noted.

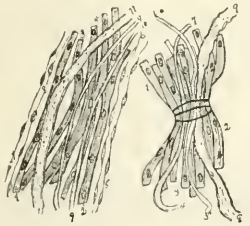

FIG. 2.—The bundle of nerves to the left in the figure is drawn from a cat's peritoneum, and represents a very general condition of nerve bundles found in the peritoneum. The main bundle consists, first, of Remak's fibres, 1, 2, 3, 4; second, of non-medullated lateral fibres, 5, 6, 7, 8; third, of medullated nerve fibres, narrow and wide, 9, 10, 11. The cut to the right in the figure represents a bundle of Remak's fibres from a cat's mesentery, acted on by acetic acid and gold chloride. In the Remak's bundle there are three medullated nerves, two narrow ones, and one wide one. Three bands of elastic fibres are preventing the bundle from expanding; 1, 2, 3, Remak's bands, nucleated; 4, 5, 6, 7, two narrow medullated nerves; 8 and 9, a wide medullated nerve.

Take of acetic acid 1 part, and of H_2O 200 parts. Of this mixture take 1,000 parts, and add 1 part of gold chloride. Place in the solution the small portion of the peritoneum whose nerves are sought for, for fifteen to twenty-five minutes; after which begin gradually to remove small pieces of the specimen into a solution of acetic acid, 1 part to 200 or 400 parts of water. Allow the specimens to remain in the acidulated water from a few to seventy-two hours, or even longer. To examine them, snip off small pieces of the peritoneum, and mount in glycerin and place in the sunlight. The specimens are valuable to study for about fifteen days, showing during that time many changes. It is of the utmost value to examine specimens which have been in the acidulated gold-chloride at various periods of time. Very different phases of nerve outlines may be observed by this method. Gold-chloride specimens present the most brilliant and beautiful structures seen in histology.

The peritoneum to select for examination of its nerves is, first and above all, that portion located in the cisterna lymphatica magna of the frog. Any other locality may be selected, but for ease of demonstrating typical nerves in the peritoneum no locality is equal to the wall of the frog's lymph sac. The reason that the peritoneal nerves are so easily and certainly demonstrated in the wall of the lymph sac is (*a*) because the lymph-sac wall is almost devoid of blood-vessels, and (*b*) there is scarcely a trace of elastic fibre. The nerves, though known by their contour, are easily confounded with blood-vessels and elastic fibres. However, the muscle cells found in the wall of the lymph sac, appearing embryonic in type, lend some slight confusion in the examination. The omentum, centrum tendineum, mesentery, and ligamentum latum of the rabbit are excellent localities for investigations of the nerves of the peritoneum: but the kitten's mesenteric or omental peritoneum is the best afforded by any of the mammals for the study of nerves.

In the peritoneum we have three forms of nerve fibres, viz.: (*a*) The non-medullated, nucleated nerve fibres, *i.e.*, the naked nucleated axis cylinder. It consists of a finely fibrillated cord, on which may be observed swellings (nuclei) at short intervals. It is the primitive axis cylinder, a continuous, non-interrupted, immeasurably fine, fibrillated bundle. (*b*) There are the fibres of Remak, consisting of a large axis cylinder, *i.e.*, a bundle of fine, original, primitive, naked, axis cylinders, united into one. Also, this large axis cylinder is surrounded by a very fine nucleated sheath. The large nuclei on the sheath are made visible by reagents, as gold chloride or acetic acid. This sheath is known as the neurilemma or primitive sheath, or sheath of Schwann. (*c*) There exist the medullated nerves, which consist of three parts—the axis cylinder, the neurilemma (Schwann's sheath), and the so-called

medullary sheath (the white substance of Schwann). The medullary sheath is of an albuminous and fatty nature, and doubtless acts as an insulator for the delicate axis fibre and nucleus (Fig. 2).

All nerve fibres are non-medullated in the embryo; so that the medullary sheath is an acquisition of development, and is not in adult life a constant factor in the peritoneum.

1. The primitive nerve fibre, the naked axis cylinder, the axial fibre, or axial band, the essential portion of all nerve fibres is definitely demonstrated by the reagents, Ag. No. 3, osmic acid, but especially by gold salts. In this form of naked axis cylinder in the peritoneum it is surrounded by no sheath—neither the medullary sheath nor the neurilemma. The axis cylinder undergoes no interruption from the point where we discover it to its termination. It is a direct and far-reaching extension of a nerve cell. In the peritoneum this form of nerve fibre is found extensively distributed along the blood-vessels. It is quite frequently found along the edge of bundles of medullary nerves, or on the edge of bundles of Remak's fibres in the walls of lymph sacs of frogs, and in the nerve bundles coursing through the mesentery.

It must not be overlooked that the naked axis cylinder nearer to its point of origin, *i.e.*, toward its prox-

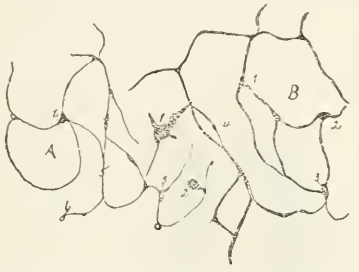

FIG. 3.—*A*, Drawn from the peritoneal ligaments of the large bowel and bladder of a frog. Non-medullated nerves a network by contact. The nerves end in bulbs, connective-tissue corpuscles, and in an obscure way in the tissue. Acetic acid and gold chloride preparation. 1 and 2, connective-tissue cell, in which a nerve ends; 3 and 4, nerve cells; 5, nerve loop by contact; 6, nerve ending and bulb. *B*, Drawn from the mesentery of a frog. It represents a network by contact of non-medullated nucleated nerves, which end in bulbs, connective-tissue corpuscles, and apparently on vessel walls. Acetic acid and gold chloride preparation. 1, 2, 3, nerve cells; 4, a round bulb on the course of a nerve.

imal end, may possess a medullary sheath. We can observe that the medullary sheath disappears and the nucleated axis cylinder alone is left. This is not only true for the wall of the frog's lymph sac, but for other portions of the peritoneum. So far as I have been able to trace such nerves in the peritoneum outside of the lymph sac, I could note the loss of the medullary sheath. In fact, it is easy in the kitten's mesentery to demonstrate a medullary nerve in the peritoneal membrane outside of the wall of the lymph sac. In the peritoneum the naked axis cylinder possesses fusiform or spindle-shaped swellings at short intervals. This swelling is granular, and shows a nucleus or ganglionic nerve cell. The naked axis cylinder with its nucleated granular swellings is easy to demonstrate with gold chloride and acetic acid, in the peritoneum covering the wall of the lymph sac in frogs, and almost equally easy in the kitten's and frog's mesentery. There it is most typically observed running near or approximately near to the edge of bundles of nerve strands composed of medullated and Remak's nerve fibres. Curiously, the naked axis nerve fibres almost always appear at the outer edge of the bundles of nerves, scarcely ever in the midst of the bundles. Again, in the peritoneum covering the lymph sac, the nerve fibres will branch off into the lateral tissue and end in some obscure manner. It often disappears suddenly. This sudden disappearing may be due to an acute bending of the nerve fibre between other tissue; it may be due to a flattening out of the nerve, so that it becomes transparent. The nerve may disappear suddenly and reappear as suddenly at a distant point. The disappearance may be due to non-uniformity in coloring the nerve fibre, the non-transparent portion not responding to the coloring reagent. Finally, the fine nerve strand may have been torn in the preparation, and we may have lost sight of its continuity.

The above factors obscure the demonstration of the definite nerve ending in the peritoneum. In other parts of the peritoneum the naked axis cylinder may be traced to the various structures, but the fibre appears to end sometimes in a long, immeasurably fine thread, like a long-drawn-out dagger. One can trace the nerve fibre to the transverse nerve cells of a blood-vessel, but no bulbous end or plate comes in sight. In short, it seems to end in tissue, like the tails of seminal spermatozoa.

If one be working in a part of the peritoneum possessed with a rich supply of elastic fibre, it will be found almost a necessity to swell the ground substance by allowing the portion of peritoneum to lie in acetic acid, 1 part to 300 to 500 parts of water, for from twenty-four to fifty hours. Doubtless the trained expert will scarcely be deceived by the contour of a nerve fibre, but the inexperienced would better bring to his aid the acetic acid, for a fibre of extreme fineness is easily covered or obscured by dense surrounding tissue. Some say that by the addition of carmine to the nuclei and the fibres the nerve will be colored, yet it cannot be denied that the nuclei and connective-tissue fibre will also be colored. All this will add confusion. Gold chloride prominently attacks the nerve alone, and hence makes conspicuous the nerve alone. It is true the gold salts attack the protoplasm of cells, but by this very action the nerve shimmers through with greater conspicuity in the peritoneal tissue. It may be stated here that the writer cannot consider it always practical to transfer the photograph of nerve structures found in the peritoneum of the amphibian lymph sac to all other portions of the peritoneum. The nerve arrangement of the peritoneum over the lymph sac is not always comparable to the nerve arrangement in other portions of the peritoneum. Yet analogous nerve arrangement is met with in the peritoneum over the lymph sac and in other portions of the peritoneum. This remark applies especially to the nerve arrangement of the naked nucleated axis cylinder, the medullary nerves, and Remak's nerve fibres. So far in my investigations I have found the bundles of medullated and Remak's nerve fibres in portions of the peritoneum analogous to the large bundles of medullated and Remak's nerve fibres found in the peritoneum over the amphibian lymph sac.

The naked-axis nucleated nerve fibres form a peculiar network in the peritoneum, which must be looked on as a significant physiologic factor. This network of nerves in the peritoneum over the lymph sac is composed chiefly of nerves which were once medullated but have lost their medulla, and what one observes in the nerve meshwork is the axial fibre with various fusiform nerve nuclei scattered here and there. But one can observe the nerves starting at certain points in the peritoneum over the lymph sac as purely medullated bundles, but before the bundles have proceeded very far the nerves begin to divide and branch off as non-medullated nucleated fibres. The nucleus is what enables us to keep track of the nerve and follow it in its deviating course. However, if we turn on a very high microscopic power, the naked axis cylinder, or, better, fibre, appears fibrillated in structure. As the bundles of medullated nerve strands wind and

twist about each other as the strands of a rope, so the fibres of the naked axis or non-medullated axis wind and twist about each other. When we say a nerve divides, we of course mean that some of the many fibres of which the original bundle was composed simply deviate in another direction, for a primitive nerve fibre is an extension of a nerve cell, uninterrupted from beginning to end.

It may be asked, what is the meaning of the nucleus situated on the axis fibre? Is it the nucleus on the primitive sheath of Schwann? In the medullated part of the same nerve, *i.e.*, before the nerve loses its medullary sheath, we cannot observe the nucleus. It is only where the nerve has lost its medullary sheath that the nucleus becomes visible. It may require more investigation in the nerves of the peritoneum to decide whether the swelling on the naked axial fibre is a nerve cell or a nucleus on an invisible sheath of Schwann. It appears to me to be a nerve cell or a nerve ganglion (Fig. 3).

The subject of anastomosis of the peritoneal nerves may be here disposed of. The veins, arteries, and lymphatics anastomose, *i.e.*, they blend or intercommunicate with each other. For example, two or more branches so combine that the blood or lymph is finally conducted along one channel. Such a method of communication or anastomosis, I think, must be denied in the peritoneal nerves. No nerve strand unites with another nerve strand. If one nerve strand or fibre blends with another, it simply comes in contact with it, but the nerve strand continually preserves its own identity. One nerve fibre does not anastomose with another; it simply runs alongside of it. Yet the nerves of the peritoneum over the amphibian lymph sac and in other portions of the peritoneum form a kind of network. The meshwork of nerves is produced by the nerve fibres coursing alongside of each other, yet preserving their exact identity.

So far as regards the medullary bundles of nerves and Remak's fibres found in the peritoneum covering the amphibian lymph sac, we can transfer the condition to the other portions of the peritoneum as typically analogous. In the kitten's mesentery, by treatment with acetic acid and gold chloride I could trace the typical bundles of medullary nerves over vast areas of the peritoneum. The bundles contained from two to twelve or more strands, which continued uninterrupted from the point of discovery to the point of sudden disappearance. The non-medullated nucleated fibres could be seen coursing along the lateral edges of the medullary bundles, exactly as they could be observed in the peritoneum over the amphibian lymph sacs. The nerve strands could be traced under the endothelial plates, but they can be seen much better with the endothelia brushed off. As the cat tribe possesses a rich supply of elastic fibres, as well as a rich supply of connective tissue and blood-vessels, it is more difficult to trace the nerve bundles in the feline peritoneum than it is in the peritoneum over the amphibian lymph sac, as that is almost devoid of elastic fibres and blood-vessels. The medullated nerve bundles assume a very sinuous and wavy course in the peritoneum, while the single nerve strand is apt to assume a straight course. The nerve bundles, like the uterine artery, seem to be too long for their space: but no doubt the apparent spiral excess in length is to adapt themselves to sudden motion or stretching of the peritoneum, for the delicate nerve strands stand trauma badly.

2. The medullated nerves of the peritoneum are numerous and easy of demonstration with acetic acid and gold chloride. They are the dark-bordered, double-contoured nerve tubes. One of the best methods of preparing them is to take a kitten six weeks old, and place the various portions of the peritoneum, mesentery, centrum tendineum, and omentum in the gold chloride, 1 part; acetic acid, 5 parts; and H_2O, 994 parts, for fifteen to twenty-five minutes, and then gradually remove the small pieces of the peritoneum into a solution of H_2O, 400 parts, and acetic acid, 1 part, in which preserve for a few days. To examine, simply mount in glycerin (a very slight previous silvering aids).

Under the microscope the medullated nerve of the peritoneum presents three parts for examination, viz.: (*a*) axis cylinder, (*b*) medullary sheath, and (*c*) neurilemma. The axis cylinder of the medullary nerve is precisely the same as the naked axis cylinder which we have just described.

The medullary sheath or white substance of Schwann is a soft, gelatinous, albuminous, fatty substance, which envelopes the axial fibre as an insulator. As soon as the medullary sheath is exposed to the preparing-fluid, it assumes an irregular outline and a curdled form. The sheath appears like semifluid transparent jelly. The medullary sheath or myelin varies very much in thickness, and produces great difference in the thickness of the nerve. One can easily note the nodes and internodes of Ranvier, and frequently the nucleus of the neurilemma embedded in the medullary sheath. The medullary sheath is very compressible, and hence the medullary nerve may appear narrow at one point and quite thick at another, from the irregular accumulation of myelin.

In the immediate observation of the medullary sheath, or even twenty minutes after death, it assumes various forms and changes, especially from the preparing-fluid and from trauma. The outline becomes quite irregular. I did not attempt to demonstrate the medullary sheath-markings of Schmidt-Lanterman.

The coagulation or congelation of the medullary sheath, which is albuminous or fatty in character, produces an infinite variety in the appearance of the medullary or so-called tubular nerves. The appearance of the medullary sheath depends on the effect of the reagent, trauma, and stage of coagulation. As the coagulation proceeds, the external and internal lines (*i.e.*, the medullary sheath and neurilemma) separate more and more, while the medulla becomes more lumpy, with globular masses in it, until finally the whole medullary sheath becomes transformed into a coarse or fine granular mass, whence the whole nerve tube looks dark.

In very fresh specimens from the peritoneum the medullary sheath shows itself as a distinct line, and its peculiar contour enables one to recognize a medullary nerve at a glance. The medullary sheath absorbs water, and becomes much larger after lying some time in acidulated water.

The neurilemma, primitive sheath, or sheath of Schwann forms the outer coat of the medullated peritoneal nerve. It is a membrane on which can be observed oval nuclei at various distances. The nuclei correspond to the nodes of Ranvier. The neurilemma becomes more apparent as the medullary sheath becomes coagulated and separates from it. One finds it occasionally very difficult, if not impossible, to demonstrate the neurilemma in some of the fine medullated nerves of the peritoneum. In the fresh state, when the medullary sheath quite fills the lumen of the neurilemma, one can scarcely discern its outline. In the peritoneum the medullary nerves run in bundles of several to a dozen, or a single nerve courses alone. With gold chloride they are easily recognized by their contour, even among blood-vessels, elastic tissue, and bundles of connective tissue. The bundle may be composed alone of medullated nerves, but more generally the medullated nerves run single, two to twelve, in the large bundles of Remak's fibres. The medullary nerves appear to course parallel with Remak's fibres, yet some assume a course which is wavy, and

thus they cross and recross the Remak's fibres in the same bundle. If the bundle contain only medullary nerve fibres, they twist about each other like the strands of a rope. The medullary nerves assume a wavy, sinuous course in the peritoneum. The width of the medullary nerves of the peritoneum varies within wide degrees. Some seem to be three times or more as wide as others. They assume a broad or a narrow width; they assume a great length; in fact, the medullated nerves of the peritoneum, as far as I can observe, are as long as the specimens. This is characteristic of nerve fibres, *i.e.*, they are far-extending nerve cells, uninterrupted from beginning to end. As we note the nerves in the muscular portion of the diaphragm under the serosa, it may be observed that the medullated nerves may course in unmixed bundles and be of a very narrow type. A whole bundle of medullated nerves, mostly narrow, some wide, may be seen, without a Remak's fibre or a naked axis cylinder being in view. Radiation and lamination are noted to exist in the medullary sheath (Fig. 4).

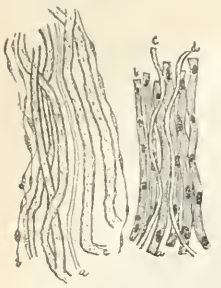

FIG. 4.—This is a figure drawn to represent a very frequent occurrence in the nerve relations of the peritoneum. It shows a Remak's bundle, *a*, *b* (to the right in the cut), with two medullated nerves, *c* and *d*, coursing almost parallel with Remak's bands. The number of medullated nerves to Remak's nerves in the bundle varies from two to ten, as far as I count, *i.e.*, Remak's bands are from two to ten times as numerous as the medullated nerves. Remak's bands (sympathetic nerves) are nucleated in the neurilemma. The figure to the left in the cut, drawn from a cat's omentum, represents a very common condition found in the peritoneum. It consists of a bundle of medullated fibres. On the lateral edges are one or more strands of non-medullated nucleated fibres, *b*. The medullated nerves are all of the wide variety, except one (*a*), which is of the narrow variety. The nerve strands are in various stages of coagulation, and twist about each other like the strands of a rope. The nerves of such a bundle are coextensive, uninterrupted from beginning to end. They are broken in the microscopic field only by the limits of the specimen.

There are two kinds of medullated nerves in the peritoneum, the broad ones and the narrow ones. I found the narrow ones especially numerous in the tendinous portion of the diaphragm of the cat, and the broad ones especially in the mesentery of the cat. Some nerves have a smooth outline, but are distinctly in the form of large-bellied spindle forms, rapidly succeeding each other—a kind of beaded fan. Doubtless there are medullated nerves with the plastic medullary sheath squeezed or forced into smaller or larger accumulations having some relation to the nodes of Ranvier. Where the bundle of nerves makes a sudden curve or kink, some of them become ruptured, and out of the ends may be seen the jelly-like coagulated myelin substance of the medullary sheath protruding in the various forms of coagulation.

In the broad medullated nerves of the peritoneum we note especially the width and peculiar coagulated or congealed medullary sheath. Irregular fine threads may be noted in its translucent milky mass, and small varied-sized globules here and there, according to the reagent employed and the time elapsed after death. A recently presented broad medullary nerve of the peritoneum shows a heavy outer dark line and a finer inner bounding line. These two lines, the "double contour," may not be exactly parallel, from coagulation of the myelin. The inner, finer line shows breaks in it, from irregular congelation. It soon looks granular or coarsely coagulated. The congelation of the medullary sheath proceeds very irregularly, and hence different segments of the nerve may present quite different aspects. This is due to rapid changes after death and to reagents. With the progress of time after death and the application of reagents to the broad medullary nerve of the peritoneum, the outer heavier and inner finer lines gradually but irregularly separate more and more from each other, and between them or even in the centre of the nerve coarse granular appearances arise and globular masses or irregular lines may be observed. The wide medullary nerves of the peritoneum may be one-fifteen-hundredth of an inch (*i.e.*, about eighteen micro-millimetres) in diameter.

The narrow medullated nerve of the peritoneum may present an entirely different character than its wider relative. It may be only one-three-thousandth of an inch in diameter (*i.e.*, about two micro-millimetres). It may present no double contour, when it is not easy to differentiate it from Remak's fibre. It may be absolutely smooth in contour. It may present a beaded or varicose condition, and yet show an even outline. In the "varicose" condition the easily mouldable myelin of the medullary sheath became compressed into irregular masses, inducing an accumulation at one point and diminution at another point. We do not observe the same tendency to lumpy or granular coagulation in the fine, narrow, medullary nerves that we do in the broad medullary nerves. Some are so fine we cannot detect a double contour. It must be considered, as Frey suggests, that the varicose condition of the fine, narrow, medullary nerves of the peritoneum is an artificial one and does not exist in life, and hence must be due to reagents or to trauma. It is not always clear what is the cause of the varicose or beaded condition of the fine, medullated nerves of the peritoneum, for at times we may note but a single one beaded or varicosed, which will run a long distance in the varicosed condition, while adjacent nerves remain even in outline. In some portions of the peritoneum the fine medullary nerves course in thick bundles.

3. The nerve fibres of Remak, non-medullated or pale nerve fibres, constitute the greater part of the nerves of the mesenteric and omental portion of the peritoneum. Remak's fibres in the peritoneum are quite transparent, faintly striated nerves of varying size. They show nuclei at short intervals. Some consider the fibre of Remak is composed of two elements, viz., (*a*) the striated axis cylinder, and (*b*) the nucleated sheath or neurilemma. Others consider that the nucleus is simply embedded in the surface of the nerve fibres themselves. It appears to me that the Remak's band consists of: 1, a striated axis cylinder; 2, a nucleated neurilemma; and 3, more or less medullary sheath. The substance representing the medullary sheath may be very small or even not recognizable. The reason I came to this conclusion is that when certain bundles of nerves of the peritoneum were recently isolated they appeared absolutely like Remak's bands, but as the bundles were kept under observation for some days (seven to fifteen) in the light (gold-chloride preparation), there appeared faint lumpy granulations between the axis cylinder and the neurilemma. These observations led me to consider Remak's band in the peritoneum as a nerve consisting of axis cylinder, neurilemma, and a very slight medullary sheath, and that the nuclei were in the neurilemma and not embedded in the nerve fibres themselves. The axis cylinder appears to be composed of many nerve fibres, sufficient to make a bundle. There is a peculiar branching, which belongs to Remak's bands. The branching leads to the formation of a network-like or plexiform condition. This branching, it appears to me, is simply the division or deviation of some of the axis fibres, as many such occur in a bundle of medullary nerves. When the fibres of Remak branch off from the original trunk, they are entirely covered by the fine, thin neurilemma. This entire closing in of the deviating fibres of the Remak trunk by the neurilemma lends the appearance that the Remak's bundles divide and anastomose differently from the medul-

lary nerves. With this explanation, the branchings of the medullary and of Remak's bundles are exactly similar. The primitive or embryonic condition of nerves is that of no sheath whatever, the sheath being of connective-tissue origin. Some consider Remak's bands as primitive nerve fibres without sheath. But, after considerable microscopic labor on the peritoneum with osmic acid, Ag. No. 3, acetic acid, and gold chloride, it appears to me that Remak's bands in the peritoneum in the majority of cases consist of a striated, fibrillated nerve axis and a nucleated neurilemma, with a probable trace of medullary sheath. It might surprise a novice in the histology of the peritoneum to learn that one of the most difficult questions I found to decide was whether certain bundles of tissue were Remak's bands or young connective-tissue bundles. It is surprising how the bands of Remak in the peritoneum resemble connective-tissue bundles. In some cases I was entirely unable to distinguish whether a bundle of fibres belonged to Remak's nerve bands or to irregular bundles of connective tissue. The nucleus of the young connective-tissue cells often resembles remarkably the nucleus of the neurilemma of the bands of Remak. Also frequently the resemblance is intensified by the fact that the portion of Remak's fibre between the nuclei on the neurilemma is transparent, similar to the transparency that exists between two successive connective-tissue nuclei. A distinguishing trait of the bundles which often decides their histologic character is the presence of one or more medullated nerves. The amount of Remak's fibres in the peritoneum is enormous. In recently prepared specimens of the peritoneum with acetic acid and gold chloride, I have carefully counted the number of Remak's fibres and medullary fibres in a bundle, and it frequently occurs that there will be from two to ten times as many Remak's fibres as medullary fibres. At other portions of the peritoneum there will appear bundles of nerves of which every strand is medullated. The single strands of nerves are more apt to be without a sheath —simply the naked nucleated axis cylinder. Not infrequently we can observe large Remak's bundles, with two or three medullary nerves, interrupted, constricted at different localities by elastic fibres. The elastic bands resemble a bound sheaf of wheat. The acetic acid induced the Remak bundles to swell, but the elastic fibres would not yield: hence the constriction. The elements which the acetic acid induces to swell must be the connective tissue, the neuroglia tissue, and also perhaps the tissue composing the neurilemma.

In general, one cannot draw any conclusions as to function from the thickness or thinness of a nerve, unless it be that the thicker a nerve is the longer is its course. Since all embryonic nerve elements consist of nerve cells and naked axis cylinders, we must consider all sheaths as evolutionary acquisitions. All nerve sheaths are of connective-tissue origin, and serve some purpose not yet fully known. Neither the medullary sheath (the white substance of Schwann) nor the neurilemma (the primitive sheath of Schwann) is necessary for a nerve. Neither may cover a nerve in its entire length. Both may enclose the nerve a distance, and fail in some other portion. Sometimes one kind of a nerve sheath encloses the axis cylinder, and sometimes another. Both sheaths may be absent or both may be present. But we must have the axis cylinder and the ganglion cell. So far we are unable to judge the function of a nerve by microscopical observation, no matter whether it be a naked axis fibre, a nerve inclosed in the medullary sheath, or one inclosed in the neurilemma (Fig. 5).

The distribution of the nerves in the peritoneum is peculiarly irregular. It has an abundant and rich supply of nerves. The medullated nerves and fibres of Remak course chiefly in parallel bundles of from two to seventy-five or even more in a bundle. The nerve fibres do not run precisely parallel in specimens, but wind and twist about each other like the strands of a rope, and the whole bundle takes a wavy or sinuous, uninterrupted course. It is probable that the nerves in the original undisturbed bundle are parallel, and that the non-parallelism is due to trauma and reagents. The nerves form a meshwork or net simply by contact, and not by real anastomosis. It is a peculiar feature of the nerve bundles of the peritoneum when they deviate or branch off that the branching strands are liable to course in contact with strands of other bundles. It is difficult to estimate the degree of richness of nerve distribution in the peritoneum. In one field of a three-hundred microscopic diameter, I have seen as many as one hundred nerve branches; but of course that quantity is an exception. In literature I can find very little in regard to the distribution of nerves in the peritoneum. In 1851 Prof. Hubert Luschka said he found nerves constantly in the peritoneum. Some few writers quibble in regard to the nerves belonging to the peritoneal membrane or the subperitoneal tissue. Numerous nerves accompany the subperitoneal vessels, but such nerves really belong to the vessel and end on the vessel directly. The nerves contain the corpuscles of Vater-Pacini on their course. The Vater-Pacinian corpuscles (cat) are really subserous. The branches of the subserous nerves end in the serous membrane. Louis Jullien observes that the Remak's fibres of the omentum measure two to three micro-millimetres, but may acquire a width of from five to six micro-millimetres.

The ending or termination of the nerves of the peritoneum is not fully settled. We have at least two kinds, viz.: (*a*) The Vater-Pacinian corpuscles, which are terminal bulbs enveloped in numerous concentric capsules of connective tissue. In the cat's mesentery, where they exist abundantly, and I have seen four corpuscles of various sizes in one microscopical field of two hundred diameters; a nerve terminates within the Vater-Pacinian corpuscle. In shape the Vater-Pacinian corpuscle is oval, and whitish or opal in color, and varies in size from one-twentieth to one-tenth of an inch in length, and from one-twentieth to one-fortieth of an inch in width. The peduncle of the corpuscle consists of a medullated nerve. The corpuscle is attached to the nerve like a berry on a stalk. The peculiar structure, which should now be termed the Vater-Pacinian corpuscle, was well known to the old German anatomist, Vater, in 1741. About 1830 Pacini, of Pisa, appears to have rediscovered this corpuscle and given it a systematic description. Since that time Cruveilhier, Henle, and Kölliker[1] deserve especial mention for the study of these wondrous bodies. Excellent and complete papers on the Vater-Pacinian corpuscle may be found in Dr. Merkel's (1880) and Dr. Krause's papers (1884).

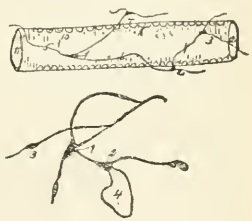

FIG. 5.—Lower portion, from a cat's peritoneum. 1, 2, 3, nerve cells; 4, a loop of a nerve, in which the two nerves approximate and run in contact. Note that the nerve cells are quite large. Upper portion, drawn from the peritoneal ligament of the gall bladder of a frog to show a very fine network of nerves ending on a peritoneal blood-vessel possessed of considerable muscular tissue. 1, 2, 3, 4, nerve ganglion and cells; 5, 6, 7, the nerve network; 8, 9, 10, the circular muscles of the artery; 11, 12, the ends of the arteriole.

The Vater-Pacinian bodies are doubtless connected with the sensory nervous apparatus. The concentric laminæ of connective tissue must be looked on merely as a capsule. Hoyer claims that each concentric lam-

[1] Monograph, 1844

ina is covered on its surface by endothelia, which can be demonstrated by the aid of Ag. No. 3. The medullated nerve which enters the Vater-Pacinian corpuscle ends in a rounded bulb. The axis fibre travels the whole length of the corpuscle in a non-medullated condition, and ends in a bifurcation or button-like knob. The numerous concentric membraneous tunics of nucleated connective tissue which enclose the peculiar axis cylinder remind one forcibly of the layers of a large onion. The central axis appears to lie in a transparent, homogeneous, semifluid substance, a kind of water bed or insulating buffer. The size of the Vater-Pacinian corpuscle in the cat's mesentery varies wonderfully. Some which came under my observation were three or four times as large as others in the same mesentery. The number of coats enclosing the axis cylinder varies in general from thirty to sixty; some are small, have few tunic coats, and resemble Krause's corpuscle. The inner tunics are much closer together than the outer ones. Each lamella or tunic consists of concentric connective tissue and elastic tissue faced by endothelia. The spaces existing between the connective-tissue tunics are regarded by histologists as lymph spaces, and hence of course lined by endothelia, made manifest by Ag. No. 3. The wonderful capsular structure of the Vater-Pacinian corpuscle must be designed to prevent traction, tension, or trauma from injuring the delicate axis cylinder, and perhaps as a collecting sensory centre. The preservation of the delicate axis cylinder of the Vater-Pacinian corpuscle is accomplished by a fluid medium (Fig. 6).

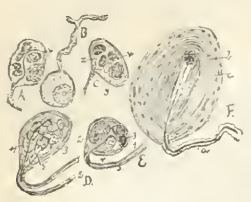

FIG. 6.—*F*, a Vater-Pacinian corpuscle drawn from the mesentery of a cat. It shows a corpuscle of concentric tunics, in which the nerve, *a*, ends. This is a medium-sized one. In the microscopic field from which this was drawn there were four Vater-Pacinian bodies of various sizes and shapes. *b* Shows the blunt end of the nerve; *c* points to the laminated concentric nucleated tunics resembling the layers of an onion. *E*, Peculiar nerve endings in a frog's peritoneum seen under high power; 1, medullated nerve stalk; 2, 3, large granular cells, with bright, round nuclei; 4, the capsule. *D*, Drawn from a frog's peritoneum after treatment with acetic acid and gold chloride, to illustrate some of the various kinds of nerve endings; 1, 2, the entering medullary stalks; 3, the capsule of the end organ containing ovoid granular protoplasmic cells (under high power); the end nerve organs in the peritoneum when successfully brought to view by reagents are very numerous, of varied shape, size, and structure; 4, 5, portions of the nerve fibre coursing among the granular cells. *A*, *B*, *C*, Various forms of nerve endings in a frog's peritoneum from one-celled to many-celled. At *A* one can trace the nerve fibre into the bulb, as at *x*. In *B* there is one big cell, but no nerve fibre could be traced in the bulb. In *C* the bulb has many cells, but the dark nerve fibres are plain at *x*, *x*, *x*. Some portions of the frog's peritoneum has scores of these much varied bulb endings.

Cyon, in 1868, was one of the first to give an intelligent description of the nerves of the peritoneum covering the lymphatica cisterna magna in amphibia. Louis Jullien continued the work in the omentum majus of man in 1872, and Finkam, in 1873, wrote an essay on the same subject. Finkam took the non-pathologic omentum majus from cadavera which came from autopsies in the Goettingen morgue. He used as reagents gold, silver, and diluted acid. He claimed that the pale fibres (Remak's bands) were only sparingly present in the omentum majus. Finkam notes, as all observers can plainly see, that the greatest bundles of nerves are in proximity to blood-vessels, and that when a nerve bundle branches the branch generally runs in the same direction as the original trunk. It may be stated from careful preparations that the nerves of the peritoneum consist of trunks composed of several bundles, which run in proximity to vessels. The trunk repeatedly divides, sending out medullated Remak's fibres and non-medullated fibres. On the Remak's bands may be seen at more or less regular distances nuclei on the sheath, which are many times longer than the Remak's band is wide. In the course of the non-medullated fibres fusiform swellings may be observed at a greater distance from each other than the nuclei on the sheath (neurilemma) of Remak's bands. It appears that the swelling on the neurilemma of the Remak's band is simply the nucleus brought to view by the gold chloride and the clearing action of acids. It is noticed by every observer that all we can see at the end of some nerves in the peritoneum is a roundish bulb. Is this bulb or end organ a relative of the fusiform swelling of the non-medullated nerve? At first I thought that the comparison of the serous covering of the cisterna lymphatica magna of the frog with other portions of the peritoneum might be proper or analogous; for the wall of the lymph sac might be considered of a germinal character, a sexual or embryonic state, some persisting part of ancient animal life. Also it might be considered that the nerves were to supply the muscle in the lymph sac. But considerable investigation has convinced me that though each portion of the peritoneum in general has quite an individuality about it, yet the several parts are quite analogous in the nerve supply. However, the fine, non-medullated, so-called nerve network, which Cyon claimed existed in the various regions of the peritoneum, is very difficult to demonstrate. Dr. Finkam claims that the end organs of Jullien are simply connective-tissue cells.

(*b*) The other form of the nerve endings or terminations in the peritoneum is more obscure and indefinite. However, it appears from microscopical observation that these nerves end: 1, in connective-tissue corpuscles; 2, around the stomata vera, especially in the cisterna lymphatica magna of the amphibia; 3, both medullated and non-medullated nerves end directly on the vessel walls; 4, in single or many-celled, capsulated, round, or knob-shaped endings; 5, in some obscure method in the connective tissue, not demonstrable by present known methods and reagents. The variously shaped and sized bulbous nerve endings are very numerous in the peritoneum.

J. B. Haycroft, E. W. Carlier, and Harold C. L. Scofield (report accompanied by a distinct figure) show that the fine medullated nerves end by being distributed along the capillary vessel. Dr. W. H. Gaskell asserts that all vascular nerves begin as fine, medullated fibres, but lose their medullary sheath in passing through nerve ganglia before they reach their termination in the vessels. The drawing presented by Haycroft, Carlier, and Scofield absolutely disproves Gaskell's assertion, for in their "cut" a fine medullary nerve, *B*, ends directly on the capillary, *A* (Fig. 7).

In 1887, E. F. Hoffmann made some investigations in the nerves of the peritoneum, and concluded that the nerves ended in connective-tissue corpuscles and in the protoplasmic cells surrounding stomata vera in the amphibian lymph sac, which is corroborative of my own investigations. In the microscopic investigations of the nerves of the peritoneum, a clinical fact is significant and impressive, and that is, with the peritoneum about equal in area to the skin, with its rich and vast nerve peripheral area, it is not to be wondered tha peritonitis produces profound reflex disturbances in the heart, kidneys, lungs, and especially the circulatory apparatus. The large number of nerves which may be observed in the peritoneum in one microscopic field of two hundred

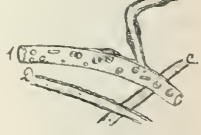

FIG. 7.—(After Haycroft, Corlier, and Scofield, reduced.) A medullary nerve ending directly on a capillary. *A*, Blood-vessel containing corpuscles; *B*, fine medullated nerve ending on the blood-vessel *A* directly; *C*, *D*, medullated nerves.

diameters is sufficiently suggestive to the diagnostician to be on his guard for local and general clinical features from peritoneal disease. The vast network of nerves, by contact in the peritoneum, allows no locality to escape manifesting irritation. A local point of infection in any portion of the peritoneum will produce local or general reflex intestinal paralysis of the most intense type. The network of nerves in the peritoneum by contact holds the whole peritoneum in an intimate and delicate balance. Under the microscope one can see in well-prepared specimens enormous numbers of non-medullated nerves, darting in various directions with the numerous fusiform enlargements, which are three to five times as large as the axis fibre. The swellings are doubtless nerve cells or ganglia situated within the axial fibre strands. Massive bundles of Remak's bands and large bundles of medullated fibres traverse the peritoneum in various directions.

The vast peritoneal network by contact is known, by its peculiar shape, different from vessels, blood, or lymph; by the peculiar triangular cell situated at a point of conveyance or divergence of the fibrillated axial fibre. Here and there in the fibrillated axial cylinder we may note the fusiform swelling or nerve cell. Also accumulations of granular material, which seem to separate the axial fibre strands in a manner similar to the fusiform nerve cell, situated at more or less regular distances from each other. The network is on a plane with the large bundles of Remak's band and non-medullated bundles, and the most typical nerve network is situated at the most distant point of the nerve bundles. The non-medullated, nucleated, nerve network is seen much better and more distinct in the mesenteries, mesogaster, and omenta than in the peritoneum covering the cisterna lymphatica magna. The vast majority of nerves ending on

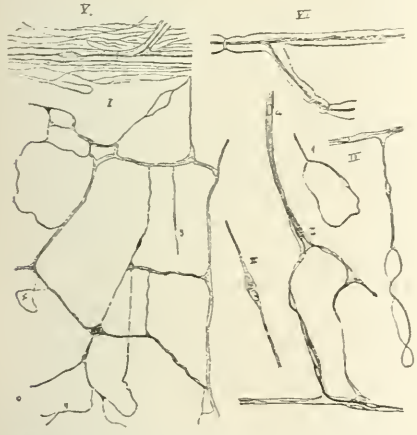

Fig. 8.—Redrawn and reduced from figures in an article by E. Cyon, 1868. The nerves were drawn, with mentioned exceptions, from the peritoneum covering the cisterna lymphatica magna of the frog. Gold preparation magnified 200. In this figure *y* and *g* show free ending fibres; at 1 the two free-ending fibres make a loop by contact. *I* Shows a distinct net or meshwork, but is a network by "contact" and not from anastomosis. *II*. A gold preparation magnified 500, from the same location as *I*. These figures show spindle-formed swellings. They must be considered as nuclei in independent bundles of nerves. *III*. A single nerve fibre with two spindle-formed swellings and nuclei, magnified 500 diameters. *IV*. Fine loops of nerve fibres from the peritoneum covering the cisterna lymphatica magna; *a* is a gold preparation; *b*, which is not marked in the figure, but is at the extreme right, is a carmine preparation. *V*. Fine nuclei bearing nerve fibres, from rabbit's omentum. Silver preparation magnified 250. *VI*. From the mesentery of a guinea-pig. Acetic-acid preparation magnified 500. Note three points on the nerve where elastic fibres present the nerve sheath from expanding.

the peritoneal blood-vessels are the fine, non-medullated nerves, with fusiform swellings on the axis fibre. For a typical sight of the nerves, perhaps the frog's gall bladder is equal to any locality (Fig. 8).

The nerves are enormous in number in the peritoneum covering the gall bladder. Doubtless this explains the excruciating pain when calculi become engaged in inducing peristalsis of the duct so highly supplied with nerves.

Here many of the Remak's bands show distinct anastomosis of the neurilemma. Of course, the axial fibres do not anastomose. In the peritoneum covering the gall bladder one can see the nucleated, non-medullated nerves pass directly to the blood-vessel wall and end there.

It may be stated that one cannot assert from observation in the peritoneum whether a nerve be sympathetic or non-sympathetic. It seems that the farther the nerve branches deviate from the main trunk bundles, the more liable they are to lose the medulla and neurilemma and remain as the primitive naked fusiform axial fibre. The extreme lateral strands of a medullary or Remak's bundle are very liable to become non-medullated and simply present the nucleated axial fibre (Fig. 9).

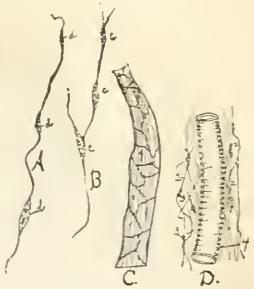

Fig. 9.—Nerves from omentum majus of rabbit. Acetic acid and water, 1 to 200, and to this mixture gold chloride is added, 1 to 1 000, in which the specimen lies for fifteen to twenty-five minutes, and is then preserved in acetic acid and water, 1 to 400, in good sunlight. This specimen I dipped for a couple of minutes in Ag. No. 3, ½ per cent. solution, before it was immersed in the acetic-acid and gold-chloride solution. *A*, *B*, Two nerve strands nucleated at *a*, *c*, *d*; *C*, a nerve running immediately under the rabbit's peritoneum. It is covered by endothelia. *I*, *I*, *I*. *D* Is a small artery with distinct muscular nuclei in it, and surrounded with a network of nucleated nerve strands; *D*, artery; 2, 2, 2, nerve stands, with nuclei at 3, 3, 3; 4, 4, the muscle cells surrounding the artery.

The nerves of the peritoneum present peculiar phenomena in the clinical field. In the first place, the peritoneal nervous periphery is not like that of the skin, though they are regions of about equal area. The skin peripheral nervous apparatus is more sensitive than that of the peritoneum. However, we know that handling the peritoneum is accompanied by considerable pain; we also know that removing gauze from the peritoneal cavity is accompanied by much pain and distress; yet this may be due to somewhat altered peritoneal nerve apparatus, as it is noted that when the peritoneum has been inflamed, has deposits on it, or the peritoneum over the bowel has been exposed from twenty-four to forty-eight hours after colotomy, such portions of peritoneum cut with little pain to the patient. The peritoneum does not perceive pain as the skin does, and the effect of disturbance of the peritoneum is pre-eminently shock. The sensitiveness of the peritoneum or its response to irritation is not equal in all regions. Doubtless this is owing to the quantity of nerve supply, and also whether the irritation be applied to visceral or parietal peritoneal nerves, for the visceral peritoneum is more highly supplied with nerves than the parietal. The sensation of the peritoneum is manifest along the lines of shock, *i.e.*, a profound effect on the vascular apparatus. The magnificent array of nerves supplying the numerous peritoneal blood-vessels, once started into action by some irritation, would profoundly affect the calibre of such vessels, and produce immediate reflex or remote effects in the distant organs. The character of the peritoneal pain is that of dulness, periodic in intensity and time.

Herpes Circinatus.—Heat was applied in cases of forty-seven patients and three nurses. Bath at 50° C. repeated each day gave excellent results.—Noir.

PRIMARY CANCER OF THE NASOPHARYNX CURED BY INJECTIONS OF ALCOHOL.

By EDWIN J. KUH, M.D.,

CHICAGO, ILL.

In May, 1896, Mr. F——, thirty-seven years of age, came to me with the following history: He had been troubled with "catarrh" from early childhood. It had manifested itself in nasal obstruction, discharge of large crusts from the nose, and in the thick speech characteristic of enlarged pharyngeal tonsil. The obstruction in the left nostril had been increasing within the last few months and forcible clearing of the nose produced epistaxis, which was, however, not a recent feature in the case, as Mr. F—— had suffered from nosebleed since his seventh year. He also expelled quantities of a viscid discharge from the nasopharynx, frequently mixed with blood; but this had also been occurring for years. There was occasional buzzing in the left ear, without conscious reduction of hearing on that side. In childhood there had been considerable earache (left ear) and undoubtedly otorrhœa, as an old perforation proved. Sixteen years ago he suffered a severe inflammation in the throat, lasting several weeks (periamygdalitis with involvement of deeper tissues?). This was followed by a phlegmon of the face and neck, and terminated after months of illness in an abscess, which was opened outwardly in the region of the cricoid cartilage. A scar remains at the point of perforation. I found both nasal chambers of abnormal spaciousness and coated with the crusty discharge of atrophic rhinitis, without the characteristic fœtor. The posterior pharyngeal wall had a recent coating of blood and was deeply congested. The post-nasal space showed almost complete occlusion by a tumor growing from the pharyngeal vault, of softer consistency on the right side and globular and hard on the left side. This growth had a layer of dry secretions. There was a slightly enlarged submaxillary gland on each side, such as we are accustomed to find in patients who are subject to inflammatory diseases of the upper throat.

Aside from a slight aggravation of the nasal obstruction and the anxiety of his impending marriage, Mr. F——'s subjective condition last May did not

FIG. 1.—*a*, Carcinoma Nests.

differ materially from the difficulty to which he had been accustomed from childhood. At the time, I made the diagnosis of an enlarged pharyngeal tonsil of unusual persistence. On a few other occasions I had seen the enlarged pharyngeal tonsil persisting in adults even into the fourth or fifth decade of life, although none of that size.

At the time it seemed as though the bloody discharge were largely due to frequent and forcible

FIG. 2.—*a*, Carcinoma Nests.

cleansing of the nose and throat. He was in the habit of snuffing water and glycerin into the nostrils, and, throwing his head backward, he rinsed nose and nasopharnyx with a column of fluid which he impelled backward and forward by gargling contractions of the palate; finally he would tilt his head forward and with an expiratory snort expel the hardened secretions through the nose.

For reasons of a personal nature the growth was not removed until July. A week after the operation there was some return of the growth, and within a month the post-nasal space was again almost completely filled with a soft bleeding mass. Sections of the tumor removed in July showed it to have the character of an epithelial cancer, the nests of concentrically arranged cells being embedded in lymphoid tissue.[1] The clinical diagnosis of carcinoma was confirmed by Prof. Nicholas Senn, and, on account of the location of the neoplasm, surgical interference was deemed too hazardous to be undertaken.

On September 15, 1896, I began with the injection of the unfiltered erysipelas-prodigiosus toxins. The preparation used was obtained from Dr. Gehrmann, of this city, and subsequently from Dr. Coley (Mr. Buxton), of New York. From five to twelve minims were injected daily through a five-inch needle attached to a Pravaz syringe, which I introduced under ocular guidance into the tumor through the nose. The usual febrile reaction followed each injection, and after ten treatments fully two-thirds of the growth disappeared. During the next few days of continued injections no further reduction in size occurred, and then, although fourteen additional injections were made (increased to thirteen or fifteen minims), the growth increased steadily in size. After the twentieth injection I excised a piece of the tumor and found the same histological character of the first growth, with a somewhat larger addition of lymphoid elements, evidently due, not to a healing process, but to inflammatory reaction. It was then decided to discontinue the toxins. Upon consultation with Dr. Senn it was decided, in view of

[1] I am indebted to Dr. C. T. Gramm for the photomicrographs.

the hopelessness of the disease and the inevitable fatal outcome, to inject alcohol into the growth, after the method of C. Schwalbe and O. Hasse. This decision was based more upon the revival of a literary reminiscence than upon a conviction of its prospective success.

The injections were begun on October 14, 1896. I used the same method as with the toxins, beginning with three minims of absolute alcohol (more could not be tolerated at first on account of the pain) and rapidly increasing to thirty minims. The reduction in size began after the seventh injection, and after the eleventh but few remnants of the growth remained. After a dozen more injections the needle would not penetrate into tissues capable of retaining the alcohol, and after a few additional attempts, at intervals of a week or longer, they were discontinued.

In February, 1897, the naso-pharynx was found both by inspection and palpation to be entirely free from growth or any suggestion thereof. A letter from Dr. Senn, dated February 23, 1897, is of interest in this connection. He writes: "Your examination of sections of the tumor confirmed the diagnosis [of cancer]. I believe that the patient has recovered completely and let us hope permanently." All that remains at present is some annoyance from dried secretions. The injections were quite painful and required all the fortitude the patient could muster in order to be tolerated. Had the monographs of Hasse been in my possession earlier, I may possibly have used thirty-per-cent. to fifty-per-cent. dilutions. At the request of the patient's family physician, Dr. H. Banga, the iodide of potassium was taken during the later injections; two ounces were given in all. As medication was not begun until shrinkage of the growth was considerably advanced, and as the cancerous nature of the tumor was above suspicion, with total absence of specific history or symptoms, it is safe to assume that the iodide of potassium stood in no causal relation to the disappearance of the neoplasm.

The marvellous success attending the use of alcohol in this desperate case (whatever the ultimate outcome may be), impels early publication as a solemn duty, in order to impress upon the profession the necessity of giving thorough trial to a method which, if proven to be of such value as it undoubtedly was in my experience, requires no commentary to emphasize its importance. Among the six cases of nasopharyngeal cancer hitherto recorded, of all of which full histories have been published, show a fatal termination. The attention of Dr. O. Hasse, of Nordhausen, Germany, to the therapeutic effect of alcohol injections was aroused by the publications of Dr. Karl Schwalbe on the treatment of goitre, hernia, angioma, etc., by parenchymatous or hypodermic injections of alcohol.

In 1872 and 1873 they applied this treatment to malignant tumors, reasoning from the analogy between the regressive metamorphosis in carcinoma reticulare (Virchow) and the contraction and atrophy of tissue in cirrhosis of the liver.

Schwalbe argued (heroically brushing aside numerous unknown factors concerning the fate of alcohol in the organism) that if alcoholism will cause formation of new connective tissue in the liver with atrophy of parenchyma, lymphatics, and blood-vessels, the direct injection of alcohol into tumors ought to do the same.

Hasse modified this method by injecting into the circumference of malignant growths, reasoning that, if the blood supply to the tumor and the export of metastatic elements from the tumor were cut off, atrophy in the tumor would result. Or, in other words, by girdling a tumor with a zone of alcohol there would result a new formation of connective tissue with constriction or obliteration of the afferent and efferent vessels. Whether this theory be correct or not, Hasse's results are truly startling. He takes cancer of the breast as his object lesson. His method is the following: A Windler syringe holding five cubic centimetres, with a needle of six to seven centimetres in length, is used. The breast is to be grasped with the full hand and elevated from the chest. The needle is introduced at the edge of the gland and when in position is detached from the syringe for one-half to one minute. If blood oozes from the needle, it is to be extracted and reintroduced, in order to avoid injecting into a blood-vessel. Then the alcohol is (acccording to the requirements of each individual case) injected into the circumference of the mamma, into the retromammary tissue, the lower free edge of the pectoral muscle, and below and between the infected axillary glands; the strength to be thirty per cent. to fifty per cent., the quantity according to the size of the tumor, varying between five and twenty cubic centimetres.

The principle to be observed is to surround the periphery of the neoplasm with the fluid, in order to induce a scirrhous contraction in the connective tissue and thereby to cause fatty degeneration of the metastatic cancer cells in the lymphatics surrounding the

Fig. 3.—*a*, Carcinoma Nests.

tumor. In this manner the author claims to reduce the blood supply to the tumor and to choke off the infected efferent vessels. The tumor itself is supposed to undergo sclerotic contraction in its interstices and a fatty regressive metamorphosis in its parenchyma. In advanced cases in which the tumor has become adherent to the pectoral muscle, the author advises immediate operation, followed by alcohol injections into the vicinity of the wound and, if necessary, into the supraclavicular and infraclavicular fossæ, in order to prevent relapse. The injections are to be made once or twice weekly in the beginning, and subsequently at longer intervals. The average number of injections amounted to one to two dozen, extending over a twelvemonth or less, each case requiring individualizing, as a matter of course. It is necessary to emphasize the necessity of following Hasse's directions implicitly in order to avoid the error of charging a method with failure due to its faulty application. Hasse reports fifteen cures in eighteen cases of breast carcinoma. The three deaths were due to the hopeless advance of the disease before treatment.

The critical reader of Hasse's publications cannot fail to be impressed with the reliability of his diag-

noses, a number of them having been confirmed by Wilms, Volkmann, Bergmann, Baum, Thiersch, Gussenbauer, Oberst.

The success in my own case, annihilating personal scepticism, justifies me in urging an unbiassed investigation of Hasse's claims. His first successes date back a quarter of a century. Ernst Brand was obliged to wait still longer before his superb results in the treatment of typhoid fever conquered an unwilling and unbelieving profession.

ANOTHER METHOD OF FIXATION OF THE KIDNEY.

By J. COPLIN STINSON, M.D.,

SAN FRANCISCO.

It must be remembered at the onset that the kidneys under normal conditions are held in place by the perinephric fatty connective tissue. If the sustentacular power of this capsule becomes impaired, a movable or floating kidney results. The left kidney reaches as high as the upper border of the eleventh rib, the right to the lower border of the corresponding rib. The tunica propria is a strong fibrous capsule. The fatty capsule is a well-defined layer and consists of the subperitoneal adipose tissue and the transversalis fascia, which is thin and ill defined in this region. The relations of the kidneys posteriorly are the diaphragmatic, the lumbar, and the iliac fasciæ.

The objects of my paper are to show that the several methods at present used in fixating a kidney are by no means perfect and to describe another method which I consider the best. An operation to be followed by a cure should fulfil the following conditions: (1) Restore the kidney and surrounding structures durably to their normal positions and relations. (2) Not interfere with the functions of the kidney, *i.e.* the operation should not be followed by pain, hæmaturia, nephritis, abscess, etc., of the kidney or its surroundings. (3) Not be followed by any other untoward symptoms, *e.g.*, slow-healing wounds, sinuses, large and painful cicatrices, etc. (4) Have a mortality at or about nil.

The following operation I consider fulfils these indications and overcomes the objections to the operations hitherto described. The patient is placed in the lateral position on the opposite side, with a hard round pillow under the loin. An incision is made along the outer edge of the erector spinæ from the twelfth rib to the iliac crest. It divides the skin, the subcutaneous tissues, the latissimus dorsi, fibres of the external and internal obliques, and the lumbar fascia for the whole length of the wound. If fibres of the quadratus lumbarum overlap the line of incision, draw them aside, next dividing the anterior layer of the lumbar fascia. The fatty capsule now comes into view, and is lifted with forceps and incised vertically to within one-half an inch of the upper and lower borders of the kidney, the index and middle fingers of one hand being introduced to ascertain the position of the kidney, etc. The fatty capsule is then stripped off on each side, for about one-half an inch, exposing well the tunica propria. If there is an excess of the fatty capsule, take up the slack by removing the redundant tissue, leaving only sufficient of the fatty capsule so that its cut edges can be brought together, later on, by nature without tension. Next the patient is thrown into the Trendelenburg position. With pelvic elevation we have gravitation in our favor, and with a few manipulations, after separating adhesions if any exist, the kidney can be readily brought out of the wound, inspected, palpated, etc., and restored to its normal position, where it is fastened in the following manner:

The first stitch is inserted at the upper angle of the incision, close to and parallel with the lower border of the last rib. The needle armed with chromicized tendon pierces the inner lip of the lumbar fascia and the fatty capsule about one-half an inch from their cut edges. The needle then pierces the tunica propria, along and under which it is carried for about one-half an inch, when it is brought to the surface. The suture should not include any of the kidney substance proper. The needle is next inserted into the outer lip of the fatty capsule and the lumbar fascia, emerging about one-half an inch external to their cut edges. The suture is then tied, a square knot being used.

The second suture is introduced at the lower angle of the incision and includes the structures as above, *i.e.*, lumbar fascia, fatty capsule, and tunica propria. This suture is also tied. Two to four more sutures are introduced in a similar manner, at equal intervals between them. These interval sutures are left untied for the time being. The cut edges of the fatty capsule and the lumbar fascia are brought accurately together with a single layer of continuous chromicized tendon. The interval sutures are now tied. The patient is lowered to the horiontal position and the cut edges of the muscular layers are accurately sutured in separate layers with fine chromicized tendon or chromicized catgut, and the skin is closed with fine silk without drainage.

Dressing and after treatment: Bichloride-of-mercury gauze held firmly in place by long strips of adhesive plaster, then a layer of cotton and a snug binder. Dress the wound on the seventh day, or earlier if there are indications; apply dressing, etc., as before. Keep the patient in bed two weeks. If primary union is not obtained, do not allow him out of bed till cicatrization is complete. The firm dressings are removed one month after the operation. For passing the stitches under the tunica propria a straight dull Hagedorn needle should be used. With little practice the needle can be readily guided along under the investing capsule of the kidney without including any of the glandular tissue.

During the past few years several methods of stitching the kidney have been described and used. The following are the principal:

1. The method described by Keen, in the "American Text-Book of Surgery": "Pass four to six sutures of silk through the capsule and a portion of the kidney tissue, then through the adjacent fascia and muscles, knotting them and cutting them off short, with or without drainage."

2. Edebohls', in the *Virginia Medical Monthly*, February, 1896: "Incision and stripping off the capsule proper, which is doubled back, with stitching of the raw kidney surface to the raw edges of the lumbar muscles; the stitches of chromicized catgut pass through the muscles and fascia of the back, the fatty capsule, the inverted capsule doubled on itself, and the kidney substance itself; passing a drain of several strands of worm gut along the raw kidney substance for drainage, and to form firm cicatricial union by irritation of the raw kidney substance and the contiguous deep tissues of the abdominal wound."

3. Reineboths', in the *Centralblatt für Chirurgie*, No.

20, 1894: "Suture of the fibrous capsule with catgut to fix the lower half of the kidney: to fix the upper half, the capsule is slit up at the posterior edge of the organ, and is loosened as far as possible from its attachment to the kidney, with packing of the space thus formed with iodoform gauze, which is also pushed up high between the exposed kidney substance and the diaphragm; the rest of the wound is packed, the packing remaining for several weeks, and its removal discloses two granulating surfaces, which after a time become attached."

4. Senn's which he thinks ought to be used in bad cases: "Two silk sutures are passed through the capsule at the upper angle and fastened to the periosteum of the twelfth rib; two other sutures are passed through the capsule at the lower angle and fastened to the lumbar muscles; the wound is widely separated and packed with iodoform gauze, which is carried as far as possible around the kidney. By this method the surface of the capsule becomes covered with granulation tissue. This anchors the organ to surrounding parts, becomes converted into fibrous tissue, and contracts. The packing is removed in one week, and the wound is allowed to heal."

I enumerate the above methods to show wherein they differ from one another.

After a study of eight nephrorrhaphies, seven of which were performed at the New York Post-Graduate Hospital while I was house surgeon, the other since I left that institution, after a due consideration of the surgical and pathological anatomy of the kidneys, and after a *résumé* of some of the literature of the day, I have reached the conclusion that all the above enumerated methods are open to serious objections.

Primary, firm, and durable union should be considered of first importance in our operations: hence the buried suture and ligature materials are of great importance. Many failures are due to the use of sutures, *e.g.*, ordinary catgut and tendon, that are absorbed before the union is firm and durable; to the use of non-absorbable sutures; to improper suturing, or to the use of gauze packing or other drains.

The structures dealt with in nephrorrhaphy are in the main tendino-fibrous, requiring several weeks for firm and durable union. Non-absorbable sutures, *e.g.*, silk, wire, worm gut, etc., should not be used, as they all, at times, even when the wounds heal by primary union, act as foreign bodies, form wandering or dead sutures, or work their way to the surface, producing slow-healing, painful, and troublesome sinuses. Cases have been observed in which patients have been incapacitated for weeks on account of abscess or sinus formation; at times repeated operations have to be performed to remove the sutures, and still later a second nephrorrhaphy to restore the relapsed organ to the normal position.

It was only recently I saw in consultation a patient who had been operated upon for floating kidney, after the technique and method of operation described and commended by Edebohls before the New York Obstetrical Society, April 18, 1893. The patient was incapacitated for weeks from sinus formation. Several operations had to be performed to remove the sutures; the kidney relapsed into its pathological position, and another operation will have to be done to cure the patient.

The use of gauze packing or other material to produce irritation, granulation, etc., I consider crude and unscientific. Methods involving this principle should be avoided, as the wounds heal slowly, and after cicatrization is complete such tissues yield rapidly on account of their poor blood supply, etc., and when relapse does occur there are, at times, present such deplorable symptoms that no support can be worn with comfort, while a second operation is rather difficult and dangerous. The principles of such methods are wrong in theory and, I think, no longer justifiable in practice. The stitches used to anchor the kidney should not include any of the secreting structure. Frequently they cut either partially or completely through the friable substance, and at all events, whether tied tightly or loosely, they cause irritation, giving rise to pain, albuminuria, hæmaturia, etc., which are likely to increase the gravity of the operation and may do irreparable damage. It is a somewhat dangerous and altogether unnecessary procedure, and I am sure better results can be obtained by not including any of the glandular structure. The opening and stripping back of the tunica propria, with stitching of the raw kidney to the muscles of the back, strikes me as being totally unscientific and unphysiological. The formation of adhesions between the tender kidney surface and muscles that are actively contracting should be avoided, as it gives rise, in some cases, to irritation, pain, tenderness, etc., in all the structures involved in adhesion. Fixation of the organ by adhesion between the tunica propria and the fatty capsule and the lumbar fascia I consider fulfils every indication. It is dangerous, at times impossible, and altogether unnecessary for the needles and sutures to include the periosteum of the last rib. The needles are liable to break, and very often the periosteum is not included. The stitches which fixate the kidney should not include any of the muscles, as at times the contractions of the latter cause irritation in and around the stitches, giving rise to pain, thickenings, infiltrations, etc. So many untoward symptoms, *e.g.*, pain, tenderness, albuminuria, hæmaturia, perirenal abscesses, sinuses, pneumonia, phlegmasia alba dolens, neurasthenia, hysteria, etc., frequently follow nephrorrhaphies, that the operation has been abandoned by some scientific surgeons. To show the pain, etc., that may be present after any of the methods of operation I have enumerated, I quote the following, from an article on cases illustrative of renal surgery, in the *Boston Surgical and Medical Journal* of July 2, 1896. "During the first six days the patient suffered a degree of pain such as I have never seen follow any surgical operation. The urine diminished in quantity, and it was feared to give large doses of morphine, such as would have been required to stop pain. She had subcutaneously doses of one-fourth grain, three or four times in the twenty-four hours, but they were almost without effect, and the only relief to pain was found in the sitting posture, and the patient could not be kept on her back in consequence."

Now as to the method of operation I have described in my paper, the Trendelenburg position, with the patient on the side, allows, with few manipulations, the inspection, palpation, and restoration of the kidney to the normal position. The removal of the excess of the fatty capsule takes up the slack in this structure. The chromicized tendon sutures through the lumbar fascia, fatty capsule, and tunica propria hold the kidney primarily, firmly, and durably, without interference with its functions, or those of adjacent structures. The approximation of the cut edges of the fatty capsule and the lumbar fascia with a single layer of chromicized tendon brings these layers into close relation with each other, and when the interval interrupted sutures are also tied the kidney is fixated in close relation with the lumbar fascia and fatty capsule, by means of the tunica propria. Properly prepared chromicized tendon sutures are non-irritating, and not absorbed for two or three months, when they are replaced by fibrous tissue. The structures dealt with in nephrorrhaphy, like those in hernia operations, are in the main tendino-fibrous, requiring several weeks for firm and durable union: that is, just about the period required for the absorption of chromicized

tendon. Under these circumstances I consider that the union between the tunica propria and the fatty capsule and the lumbar fascia is sufficiently firm and well adapted to hold a kidney durably in its normal position without occasioning any untoward symptoms. In order that there will be no adhesions of the layers one to another, and that the resulting cicatrix will not be painful, tender, or unsightly, each of the cut muscular layers should be sutured separately with fine continuous chromicized tendon or chromicized catgut, and the skin with fine silk without drainage. If the operation has been antiseptic and aseptic, there is no necessity for drainage.

Materials, *e.g.*, gauze packing, strands of silkworm gut, etc., used to produce irritation, granulation tissue, etc., should be avoided for the reasons already given.

In conclusion I may state that I consider that, by the operation I have described in my paper, a displaced or movable kidney can be restored firmly and durably to the normal position and relations without interference with its functions and without the operation being followed by any untoward symptoms.

326 Kearny Street.

SOME REMARKS ON ADENOIDS, WITH CASES.[1]

By JOHN A. JAMES, B.Sc., M.D.,

Professor of Diseases of the Ear, Nose, and Throat in the St. Louis College of Physicians and Surgeons; Rhinologist and Laryngologist to the Missouri Pacific Railway Hospital and the St. Louis Baptist Hospital; Consultant for Diseases of the Ear, Nose, and Throat to the Merchants and Manufacturers' Hospital, Episcopal Orphans' Home, St. Joseph's Orphan Asylum, etc.

It is a matter of great gratification that a very general interest is beginning to be taken by the profession at large in the subject of hypertrophy of the pharyngeal tonsil, a condition generally described by the term adenoids. It is extremely satisfactory to note the increasing importance given to this subject in text-books devoted to diseases of the upper air tract. If we compare a text-book of even seven or eight years ago with one of to-day, we are struck by the fact that the scant mention given to hypertrophy of the pharyngeal tonsil in the older book has given place to an elaborate chapter in the later work, describing minutely the condition, its effect, and the means for its cure. It is because of the great amount of literature that has been written upon this subject in the last few years, that I purposely avoid the discussion of the anatomical and other well-known aspects of the condition, choosing rather to ask your attention to the clinical features of a few of the more striking cases selected from my record of patients operated on, and calculated in each instance to show some form of disturbance, reflex and otherwise, dependent upon the existence of adenoids.

Case I.—Bernard S——, aged fifteen years, Little Rock, Ark., was referred to me by Dr. Jenkins, January 25, 1895. He gave a history of "catarrh" since early infancy, characterized by much discharge and a correspondingly great effort to clear his nose by blowing and snuffing at frequent intervals. He had had frequent earache, and was at times quite hard of hearing. He presented the typical adenoid face, speaking with the "dead" voice, breathing with parted lips, snoring, and suffering almost all the time with symptoms of a common cold in the head. A year before his visits to me he had been seen by a gentleman who, examining his nose and finding it stuffy, applied the galvano-cautery on eight different occasions. No relief from the mouth-breathing resulted, but ever since that time he had frequent and spontaneous nose bleeding, with formation of large crusts in either nostril. Examination showed the nose filled with dry, scaly crusts, without fœtor. The turbinate bodies had been so reduced in size as to render the nostrils simply two holes in the head. The pharynx was dry and glazed, and an enormous mass of adenoids filled the nasopharyngeal space. It was explained to his uncle, who accompanied him, that no relief could be extended in the way of restoring the destroyed turbinate tissue, but that the so-called "catarrh," the mouth-breathing, and the aural disturbance would be entirely relieved by the removal of their cause—a hypertrophied pharyngeal tonsil. Two days later the adenoids were removed by the use of the forceps and the curette. That day the patient breathed freely, his voice was clear, and his facial expression bright. He was given a stimulating application for the turbinate surfaces, and four days later he returned home. Half a year later his uncle stated there had been no recurrence of the mouth-breathing or catarrhal secretion, but that the tendency to crusting still existed, though in a lessened degree.

The above case has been exactly duplicated in several instances. A child suffers from so-called catarrh. An examination of the anterior nares is made. The turbinate bodies are discovered to be abnormal in size, and powerful cauterizing agents are applied, with the object of relieving the supposed hypertrophy. Now, almost all patients with adenoids present on anterior rhinoscopy the appearance of hypertrophic rhinitis; but that it is a purely vascular turgescence of the turbinate bodies is shown by the application of cocaine, when the nostril quickly resumes its normal lumen. The cauterization of a turbinate body is never to be done without proper deliberation; and, in the case of children, I believe we are right in practically forbidding the cautery, instances of true hypertrophy in children being few and far between. In the case cited, and in several similar ones, the destruction of the most important function of the nose—namely, moistening and warming of the inspired air—has been forever destroyed. Had the operator but used the rhinoscopic mirror or passed his forefinger up into the nasopharyngeal space, he must at once have found the mass of adenoids.

Case II.—Bessie S——, aged eight years, referred by Dr. Keeble, December 10, 1896, had been a mouth breather all her life, her breathing being distinctly audible several feet away. She was thin and anæmic, the appetite was poor, and her sleep restless and broken. All her life she had been in the habit of wetting the bed every night. Examination disclosed the presence of faucial tonsils of moderate size, and a well-developed pharyngeal tonsil. She was somewhat deaf, and there was a history of earaches. Three days later the adenoids and the faucial tonsils were removed, under chloroform. Her weight increased following the operation, and her breathing became entirely normal. Her sleep was quiet and peaceful. On the second night after the operation she failed to wet the bed, and from that date she has been entirely cured of the habit.

I select this case because a number of children having adenoids have had nocturnal enuresis, which without any treatment disappeared after the operation. It is easy to understand that mouth breathing, with its consequent discomfort and restlessness, may well figure as one of the reflex causes of nocturnal enuresis.

Case III.—Maude G——, aged seven, had been a mouth breather all her life. She presented the usual characteristics of children with adenoids. A year ago her large faucial tonsils were very properly removed by a gentleman, without altering the mouth breathing or benefiting the "dead" voice. She suffered from a nasal "catarrh," and in this condition was

[1] Read before the Missouri State Medical Association, at Sedalia, May 19, 1896.

taken to Dr. Outten, who recognized the existence of the adenoids and referred her to me. The relief following the operation, done under chloroform, was immediate and complete.

This case is cited because it is one of the many in which an assurance of relief is given, the faucial tonsils are removed, and the adenoids allowed to remain. Of course, the obstruction to nasal respiration remains as before. I urge, therefore, that, in all cases in which the faucial tonsils are hypertrophied and catarrhal and other obstructive conditions exist, a careful search be made at the same time for adenoids, and their removal be insisted upon whenever found.

Case IV.—Hoyt B——, aged eleven years, was referred to me by Dr. Morris, in January, 1895. His history was the frequent one of associated nasal catarrh, earaches, etc. He was strong, well grown, and handsome, except for a confirmed habit of mouth breathing, which had resulted in an extremely faulty arrangement of the teeth. The upper incisors projected half an inch below the lower ones, leaving them always visible beneath the apparently too short upper lip. His mouth breathing was found to be due to the presence of adenoids, which were removed. He was then referred to a skilful dentist, whose efforts to straighten the teeth will, I believe, be entirely successful. To attempt to do this without first rendering nasal respiration possible is clearly an error. It is doubly important that cases like this latter, which, especially in girls, result in great marring of personal beauty, be attended to very early in life.

Case V.—Edward H——, aged five years, was a sufferer from frequent attacks of croup, of cold in the head, and earache. He was brought to me on January 8, 1895, and a diagnosis of hypertrophy of the pharyngeal and the faucial tonsils was made. I urged an operation, which was refused by the parents. For a time an expectant treatment was followed, with the usual result—a failure. He sustained an attack of acute purulent otitis media, and passed into other hands. Some months later, coming into still other hands, a superficial operation was made upon the adenoids. In November, 1895, he had a heavy cold, accompanied by a severe croup and acute otitis media. The father returned to me, and on November 21st both the adenoids and faucial tonsils were removed. His hearing, which was noticeably dull, was restored by gentle inflation of the middle ear. He passed through the winter for the first time in his life without croup or earache.

I cite this case because it is one out of a vast number in which the subjects suffer from repeated attacks of earache and of various forms of middle-ear and mastoid disease. They go on from year to year, suffering from recurrent attacks of otorrhœa, which are treated solely through the aural speculum, and the cause of the trouble is allowed to persist. A succession of these attacks leads to the development of the exceedingly frequent cases of chronic purulent otitis media, with their accompanying necrosis of bone and polyp formation and the attendant loss of hearing.

In his classical paper on adenoids, Wilhelm Meyer stated that seventy-four per cent. of his patients suffered from some degree of deafness. Woakes goes still further, in declaring that ninety-five per cent. of children with adenoids have middle-ear disease. I believe that in every case of middle-ear disease the nasopharynx should be carefully explored for adenoids, and that these, when found, should be thoroughly removed as an early part of the treatment of the aural condition. When this is done we shall realize the truth of the statement of Halstead, that "it has been the misfortune of otology that the ear has been viewed too much through the aural and too little through the nasal speculum and rhinoscopic mirror."

Case VI.—Oscar M——, aged eleven years, Plattsburg, Mo., was brought to me, October 25, 1895, by Dr. DesMond, of that town, with the following remarkable history. His mother and three maternal uncles and aunts died of consumption, and on his father's side there were three cases of paralytic dementia. The boy had whooping cough and measles at three years; otherwise he had been well. Two years ago he fell on the floor in a convulsion, the unconsciousness persisting from one and one-half to two hours. This was followed by a period of both deafness and blindness—total and complete—lasting about three hours. At the end of that time he placed his hands to his ears, complained of a sudden severe pain there, and the hearing and sight were as suddenly restored. This attack was followed by others exactly similar in every way. For over a year he had been out of school, because he had attacks while there. He did not have them while at play, but they occurred upon coming into the warm, heated room. The coming of the seizures could not be predicted by himself or his friends. It was observed he never fell or hurt himself during the attacks. A year ago a gentleman in Cincinnati removed a small amount of adenoid tissue from his nasopharynx. His condition was not modified, and when I saw him he presented an absolutely typical adenoid face—the open mouth, the vacant look, the "dead" voice, the flat wide bridge of the nose. He was tall for his age, but somewhat thin and anæmic. The case was evidently of a hysterical character. He had been for some time under careful observation by Dr. DesMond, who had excluded various factors that might have led up to the trouble. Just what causative relation the adenoids bore to the attacks was not clear: but, after consultation with Dr. DesMond, it was decided to clear out the nasopharyngeal space. This was done, the amount of lymphatic tissue being very great. He returned to his home the next day, and I heard no more from him until March 18th, six months after the operation, when he entered my office. He had had no attacks since the operation, he breathed easily and freely through the nose, his appearance was bright and healthy, and he had gained fifteen pounds.

Case VII.—On December 4, 1895, I was hurriedly sent for by Dr. Garcia, to do a tracheotomy on a three-year-old child. The patient, a fat, short-necked little girl, had suffered for three days from a severe attack of croup, which had failed to respond to all the remedies. Her face was pale, there was extreme inspiratory dyspnœa, the respiration was 45, the pulse was quick and weak, and the surface of the body was bathed in a cold perspiration. The case was certainly an alarming one; and to one who had to attempt a tracheotomy on a child at once so young, so short-necked, and so fat, not a promising one. On attempting to use the laryngeal mirror, it was found impossible by reason of the presence of a pair of large faucial tonsils. The forefinger was passed up into the nasopharynx. The space was filled with adenoids. The child had been a confirmed mouth breather all her life. A hurried consultation was held. It seemed worth while to attempt the removal of the faucial tonsils and adenoids before undertaking a formidable tracheotomy. The faucial tonsils were quickly guillotined and the adenoids thoroughly removed by forceps and curette. In less than five minutes the hemorrhage had entirely ceased, and the exhausted little patient slept with closed lips and without a trace of croup or laryngeal stridor. Fearing to leave her, she was watched for half an hour, but continued to sleep quietly. She was seen twenty-four hours later. The parents reported that she had slept the entire night, with closed mouth and no symptoms of croup.

This case is, I believe, entirely unique in teaching that, in some cases at least, an immediate adenectomy

and tonsillectomy may suffice instead of tracheotomy in cases of laryngeal croup of spasmodic character. The explanation lies in the fact that in mouth-breathing children the unmoistened inspired air dries and renders irritable the mucous surfaces of the larynx, thus predisposing toward laryngeal spasm. The restoration of nasal respiration results in proper moistening of the inspired air, with consequent relief from the spasm. A careful observation of many croupy children has shown me that nearly all of them have adenoids or hypertrophied tonsils, or both.

The operation for the removal of adenoids is, when done with proper care, a simple one. The instruments required are a good mouth gag, preferably O'Dwyer's, and several forms and sizes of forceps and curettes. The steps of the operation are as follows: The patient being anæsthetized and in a good light, the mouth gag is introduced on the left side and held by the assistant. The operator, standing on the right side, introduces his left forefinger into the nasopharyngeal space as a guide. The forceps are introduced and the mass of adenoids is seized and removed. This is repeated as often as is necessary to clear out the space. Some shreds of lymph tissue will remain. These should be thoroughly scraped out with some form of the Gottstein curette. An ideal result contemplates the removal of the entire mass. The hemorrhage is generally profuse for a minute, then ceases spontaneously. Should large faucial tonsils exist, it is best to guillotine them immediately before attacking the adenoids. A few simple dressings complete the after-treatment, although such cases should be kept under observation for some time, to note possible recurrences. Many of them are in bad general health, having enlarged glands all over the body. To these I have given with excellent effect the syrup of hydriodic acid in liberal dosage, as being at once efficient in action and pleasant to the taste. The associated deafness, which exists in most adenoid children, begins a spontaneous improvement in many cases; and in almost every one of them a gentle inflation of the ear is enough, after a few repetitions, to restore the normal hearing-distance.

The patient, if under fourteen years, should always be chloroformed, and the anæsthesia should be more profound than is generally employed. There are two reasons for this—first, that the administration of the anæsthetic is suspended as soon as the operation is begun; and second, as pointed out by Dr. Keeble, who has efficiently assisted me in a number of operations, that the nasopharyngeal reflex being more delicate than the conjunctival, we are often misled by the latter test and forced to suspend the operation while more chloroform is being given. For older patients no anæsthetic is required. I have carefully questioned many of them, and have been assured, in nearly every instance, that the operation was almost devoid of pain, the discomfort of having the instrument in the mouth being the chief annoyance. Further, I urge that the slight danger of anæsthesia in children is more than outweighed by the fright and shock attendant upon the performance of this brief though bloody operation without it. Again, the operator is allowed more time in which to do his work carefully and completely. To do a quick, hurried operation on a struggling child is to leave the way open, in most cases, to a recurrence of the growth. The truth is attested by two of the cases herewith reported as having been operated on by others, and by several of my own operated on before I learned to insist upon thorough anæsthesia. The danger to the Eustachian tubes and other adjacent structures is greatly lessened under chloroform. But a short time ago I showed to Dr. Summers, who is present to-day, a young woman of eighteen, in whose nasopharynx the Eustachian tubes were separated by an interval of less than half an inch. The careless use of wide cutting instruments in such a case must have resulted in great laceration of the Eustachian orifices and consequent deafness. In this case a slender forceps and a narrow curette removed the growth.

In conclusion, I wish to protest against the weak and careless policy so often indulged in, of allowing children with adenoids to grow up in a condition of mental and physical inferiority to their playmates, and of thus fixing upon them, in their adult life, infirmities and disabilities which no skill can entirely remedy—a policy which is justified by the bad advice so often heard, that "the child will outgrow the trouble."

2836 LAFAYETTE AVENUE.

MERYCISM.

BY LEWIS S. SOMERS, M.D.,

PHILADELPHIA, PA.

THE voluntary act of regurgitating the food for the purpose of remastication is the normal method of digestion in a large class of the lower animals. To this condition the name merycism or rumination has been applied, the latter term being used most frequently and often wrongly, the condition being erroneously associated with involuntary regurgitation. Occurring occasionally in the human subject, it is most frequently seen in degenerates or neurasthenics, or as the result of prolonged mental strain, and usually bearing a remarkable parallelism to the degree of the neurasthenia. Nacke has reported his own case; at the age of thirty years, becoming neurasthenic from excessive mental work, he was subject to periodical attacks of merycism.

The mechanism of the condition starts with the act of regurgitation, which is preceded by a rapid inspiratory effort and simultaneous closure of the glottis, during which the diaphragm is forced downward, with contraction of the stomach walls, so drawing the contents of the stomach through the cardiac orifice; this is immediately followed by a deep expiration to prevent the return of the food. The stomach contents are regurgitated to the mouth in small quantities, then masticated and again swallowed, the process being repeated at intervals until complete digestion has ensued or another meal been partaken.

The following subject, presenting the various phenomena of merycism, applied to the aural clinic of the Union Mission Hospital, October 11, 1893, for relief from progressive impairment of hearing:

Albert McC——, male, aged five years. Family history is negative, except as to an uncle and cousin on the maternal side, neither of whom could talk until after their sixth year.

Personal history: Born at term, nearly asphyxiated on account of prolonged labor; with this exception delivery was normal, no instruments being used. Attention at this time was attracted to the large size of his head. He was unusually intelligent as an infant, and with the exception of an indefinite history of coryza and convulsions at three months of age, was healthy until his third year, when he had measles. Previous to this he could talk as well as any child of the same age, and hearing was normal, but the rubeola was followed by a total loss of hearing without aural suppuration, and in a short time he could not talk, simply making unintelligible sounds. He has one brother, ten years of age, who is healthy. He has been well as regards general health since the attack of measles.

The boy was robust in appearance, could not talk, and presented the appearance of chronic hydrocephalus as far as the size of his head was concerned.

Measurements of the head were made, and showed a marked increase in size over the normal. The hard palate was "gothic" shaped, there was slight hypertrophy of the tonsils, and the pharynx was sclerotic. Nose, turbinates hypertrophied. Ears, both membrana tympani thickened and retracted. He could not hear watch or voice on contact, but bone conduction was normal. Under treatment hearing was restored, and he could talk fairly well.

He was then absent from the clinic for about six months, when his mother brought him back, with the complaint that "he ate his food like a cow." On questioning, it was ascertained that he would regurgitate his food and masticate it with apparently greater enjoyment than during the original eating. This was entirely voluntary on his part, and occurred at irregular intervals, but principally about one-quarter to one-half hour after meals. Frequently he would hide to avoid censure, and when found would be sitting alone, masticating the remains of a former meal with evident relish. When this condition was first noticed, true vomiting would sometimes take place from his efforts to regurgitate more than his mouth would hold; but this disappeared as his experience increased, for he soon became able to judge of the amount required to masticate at one time. Dr. John H. Dripps then saw the case with me, and made a diagnosis of neurasthenia. The patient was put on a semi-solid diet, meat in small pieces to be eaten slowly, and the mother instructed carefully to attend to his meals and use large amounts of "moral suasion." He also received the syrup of the iodide of iron and calisaya. Improvement was gradual, but at times he would apparently relapse into the former condition of merycism. When last seen, about six months ago, his mother stated that he remasticated his food only at long intervals, and she considered him cured.

A lowered or perverted condition of the nervous apparatus plays an important part in the etiology of merycism. Heredity is of some importance, as concerned in the transmission of a vitiated nerve tone. This hereditary influence was in the minds of some of the earlier writers when they laid stress on the descent of the person affected with the disorder from herbivorous parents, or thought their ancestors possessed two stomachs, like some of the lower animals. In a number of cases studied by different authors, neurasthenia was credited with being the underlying condition, and at the same time some disorder of the stomach was present. Lemoine and Linassier divide the condition into two varieties, a simple and a pathological form, while they have divided the latter form into several subvarieties depending upon the degree of dyspepsia present. Mimicry has appeared to be a factor in a few reported cases. A low grade of stomach irritation is probably present in nearly all cases, and by reflex action gives rise to the desire to regurgitate the food; this irritation may be the result of local pathological changes or simply a manifestation of lowered nerve tone.

The frequency with which merycism is seen among the insane, and the fact that it may be voluntarily produced or even suppressed, are in favor of its nervous etiology. Improper mastication of the food probably plays an important part in its etiology. Hammond describes a case in which rapid eating was productive of the condition, it being usually absent when the food was taken slowly and properly masticated. In these cases it appears to be an effort of nature to secure sufficient mastication, as when the food is regurgitated proper mastication always occurs, from the pleasure afforded the patient both by the mere act of chewing the food and by the pleasant taste associated with it.

A study of the regurgitated food has shown that digestion had not commenced or occurred to any great extent, thereby not interfering with the pleasant taste which seems to be excited. Analysis of the stomach juices has been productive of so widely varying and inconsistent results that no definite changes have been observed; in not a few cases the chemical examination showed nothing differing from the normal.

Merycism takes place usually on an average of fifteen minutes after a full meal, but the time may be delayed to over an hour and varies with the individual case, depending upon the size of the repast, or the haste in which it was partaken, or whether severe exercise occurred immediately after the meal. The time consumed in the second is usually greater than during the original mastication, frequently lasting for several hours. The food may be regurgitated after each meal, and also at intervals during the day, while some persons with the habit will rechew the food only at special times. The condition seems confined mostly to the male sex, and exerts but little influence upon the general health, although as a natural consequence, if the habit is long continued, the stomach is bound to suffer, and if the regurgitated food is not properly masticated gastric catarrh may result. The health mostly continues good as long as the food is properly chewed and the taste remains pleasant. As soon as the taste becomes sour or acid, it becomes evident that morbid alterations are taking place in the stomach, the health then suffering.

Treatment consists in removing the cause as far as possible, and minute attention to the food and manner of eating. The patient should be directed to eat slowly and properly masticate. Solid food, for a time at least, should be prohibited, or, if used, should be taken in small amounts. An effort should be made to repress the movements which cause the regurgitation, and the dorsal or other position unfavorable to the act should be insisted on for a definite time after each meal. Gastric sedatives, such as small pieces of ice swallowed at intervals, are useful, while tonics and laxatives are of service in some cases. Strychnine and electricity should be given a thorough trial, the latter being used over the region of the stomach or internally directed to the cardiac orifice.

Progress of Medical Science.

Causes and Treatment of Abortion and Premature Labor.—Dr. Romheld (*Centralblatt für Gynäkologie*) has studied 225 cases with reference to the causes of these conditions, and has reached the following conclusions: Syphilis is the most important cause and accounts for 27 per cent. of the cases: retroflexion of the uterus is accountable for 18 per cent.; chronic metritis and endometritis, 10 to 15 per cent.; uterine fibroids, 4.7 per cent.; abnormal conditions of the placenta, 4 per cent.; anteflexions of the uterus, 3.5 per cent.; molar pregnancy, 1 per cent.: Bright's disease and lateral deviations of the uterus, 5 per cent. Constipation and anæmia are predisposing causes. Heredity does not appear to have much influence. The treatment is essentially prophylactic.

The Treatment of Prostatic Hypertrophy and Retention by Cauterization through the Rectum.—Dr. Negretto (*Gazz. degli Osped.*, December 27, 1896) reports four cases which he treated in the following way: The patient is anæsthetized after thoroughly emptying the rectum, and a rectal speculum is passed. The upper part of the rectum is plugged with gauze and under the guidance of the finger, a specially devised hook with graduates is passed into the prostate to steady it. The prostate is then cauterized over the extent required. The operation lasts

but two minutes. The bowels are kept confined and a catheter is kept permanently in the bladder for some time. A purge is given on the sixth or seventh day and the catheter is removed on the tenth or twelfth day. The patients were fifty-six, sixty-two, seventy-four, and seventy-eight years of age respectively, and had suffered from the disease for from three to five years on the average. In each case the congestion was speedily relieved and the size of the prostate notably diminished. The author thinks this method superior to excision of the vas deferens or to castration.

The Maragliano Serum.—A correspondent of the London *Lancet* writes from Rome that the Maragliano serum promises as good results in the treatment of pulmonary phthisis as antitoxin has given in the treatment of diphtheria. Because of the nature of tuberculosis the antitoxin can never assert its power so rapidly and decisively as in diphtheria. Dr. Maragliano has had most success in private practice, because in such cases the patient usually consults a physician in good time and has the comforts and careful attendance of home; in hospital practice the patient is usually far gone in the disease, his strength has been sapped by pyrexia or hæmoptysis, and his resisting power is low through malnutrition. Even in these cases Dr. Maragliano has had most encouraging success. His followers of the Neapolitan school, though slow to adopt this treatment, have not been less successful, and Dr. De Renzi, the dean of Italian clinicians, announces that he has had forty cases of cure by the Maragliano serum in his wards and equally gratifying results in private practice. He advises one not to despair even though two hundred injections have failed to produce the desired effect. He observed that improvement was noticeable even in the most intractable cases, and one need only suspend the treatment for a short time to witness the rapid exacerbation of all the symptoms and hastily to resume the injections. Dr. De Renzi has inoculated phthisical patients with five milligrams of Koch's tuberculin and has obtained a strong reaction; but applying the same treatment to patients already under the Maragliano treatment the reaction was less marked, showing that they had been immunized against the "protein tubercolari." In proportion as he increased the number of injections of the Maragliano serum he augmented the immunity against the tuberculous poison, until after thirty or forty injections the reaction to the same dose of tuberculin was scarcely appreciable. According to Dr. De Renzi's opinion there is no remedy for phthisis equal to the Maragliano serum; it seldom fails to relieve, and, if applied in time and persevered in, it almost invariably effects a cure.

Obstructed Labor Due to Congenital Cystic Disease of the Kidneys.—Spence (*British Medical Journal*, March 13, 1897, p. 651) has reported the case of a woman, forty-one years old, married seventeen years, who had borne five children at term, and had had one miscarriage, whom he was called to see some twelve hours after rupture of the membranes, followed by continual dribbling of liquor amnii, and weak and inefficient pains at long and gradually lengthening intervals. The previous labors had been tedious, but otherwise normal. The os was found to be dilated to about the size of a silver quarter-dollar and the head was presenting normally. The head slowly descended and the os gradually dilated. The labor made but little progress until a full dose of ergot was administered, when the pains became stronger and more frequent, and the head was extruded from the uterus. The umbilical cord was wrapped once about the child's neck, but it was readily displaced. The body remained firmly impacted in the uterus, and for a time could not be dislodged, even with the aid of traction upon the head, and subsequently upon the axillæ. Finally, the arms were brought down, and then strong and continuous traction resulted in the delivery of the fœtus. As soon as the head was born the child gave three or four gasps, but it was dead upon the completion of delivery. The child, a female, was fully developed, weighing nine and one-half pounds, and measuring twenty and one-half inches in length. The abdomen was enormously distended, from the presence of two large, indurated masses, one on either side, occupying the flanks, and almost meeting in the middle line. They were movable, and could be easily manipulated through the abdominal parietes. On opening the abdomen the masses proved to be enormously hypertrophied and cystic kidneys, weighing twenty-five ounces.

Secretion of Cerumen.—Dr. Mishkin (*Atlanta Medical Journal*, January 30th) says that an increased secretion of cerumen is usually the result of disease of the middle ear or of a catarrh of the nose or throat. It is rather unusual to find the hearing perfect after the removal of a mass of impacted cerumen; the introduction of irritants within the auditory canal increases the secretion of cerumen. Those who suffer are often the victims of misplaced efforts at cleanliness, twisting the end of a towel and screwing it into the ear. Nature is not given a chance to displace the materials it forms, but meddlesome attempts to hasten the process push back and pack inward the emerging mass, and by the irritation increase the secretion of wax.

An Analysis of One Hundred and Twenty-One Cases of Cirrhosis of the Liver.—As a result of a study of 121 cases of cirrhosis of the liver among 3,053 medical cases recorded in the post-mortem records of the Manchester Royal Infirmary, Kelynack (*Birmingham Medical Review*, February, 1897, p. 86) reaches the conclusion that common atrophic cirrhosis cannot conveniently be divided into alcoholic and non-alcoholic varieties. Most examples encountered in hospital practice occur in alcoholic subjects. Nearly 50 per cent. of the patients die directly from the effects of the hepatic lesion. More than 12 per cent. die from active tuberculosis. Tuberculosis of the peritoneum exists in a little over 9 per cent. Either active, latent, or obsolete tuberculosis is encountered in nearly 24 per cent. of all cases. Cirrhosis of the liver appears to be the commoner in males, in about the proportion of two to one. The average age at death is for males forty-five and a half years, for females forty-two years. Ascites occurs in 56 per cent. of all cases. It is usually less pronounced in females than in males. It occurs constantly in association with hæmatemesis, but the two are not to be considered as mutually exclusive. The weight of the liver averages in males a little more than fifty-three ounces, in females nearly fifty-four ounces. The liver is increased in size in 33 per cent. of all cases, diminished in size in about 61.5 per cent., and normal in size in only about 5.5 per cent. The liver varies in size in its ante-mortem and post-mortem conditions. Typical hobnailed livers are not common at the present time, although evidence of alcoholism is being constantly encountered. The spleen in cases of cirrhosis of the liver weighs on an average in males fourteen and a half ounces, in females a little more than eleven and a half ounces. The spleen is enlarged in 83 per cent. of cases, is normal in nearly 9.25 per cent., and diminished in size in 7.75 per cent. The cyanotic spleen of hepatic cirrhosis is larger and heavier than that met with in cardiac cases. Renal cirrhosis occurs in association with cirrhosis of the liver in only a little more than 18.5 per cent. of all cases.

New York, April 17, 1897.

QUACK ADVERTISEMENTS IN OUR DAILY NEWSPAPERS.

JUST now there is a great outcry against indecency in secular journalism, and the fact that certain dailies are being dropped from club lists and public libraries has with some of our lay contemporaries been magnified into the importance of State news. This is certainly a good sign of the times, and tends, although in a suspiciously interested manner, to educate public opinion in the proper direction. To the impartial observer, however, it is quite evident that the parties who throw the stones are by no means free from guilt themselves. Much of the effort to be very good is ridiculous on its face. It is, after all, the old trick to balance the beam against the mote in the journalistic eye. While all this discussion is going on concerning what is pure and the proper education of the people, no attention appears to be paid to the shameful, lying, and indecent advertisements which are so common in all daily and weekly newspapers, good and bad. The high-minded utterances of the editorial columns are so different and so distinct from the blatant lies in the rented department of the paper that they remind every casual reader of the fact that he who sups with the devil must have a long spoon. While no one will deny that such a practice is openly abetting fraud, there appears to be no effort on the part of even the most respectable periodicals to discourage or check the growing evil. In all the leading newspapers there appear regular bids from the professional abortionist, in bold defiance of all ordinary law or common decency. Many of these quacks have been repeatedly indicted for criminal practices, and their cases have been freely reported in the very papers which publish their standing advertisements. Even religious journals sell their spaces to these humbugs, and under the guise of uplifting the spirit on the one hand degrade and destroy the body on the other. The quick relief of discharges by the use of balsams in capsules needs no detailed explanation for the man with gonorrhœa, nor is "the decline of manhood" mistaken for overwork, consumption, diarrhœa, or grippe. The "female pills" appeal to the erring who become the unfortunate victims to preventable accidents, while every reader who has a womb is informed that it can never be kept healthy without the use of a notorious grandmother's tea. The illustrated idiots who are cured by snuffs, inhalations, vegetable compounds, and soaps fill the sold spaces with the most transparent lies, and carry with them the most outrageous insults to common sense and ordinary judgment. It is absurd to suppose that the conductors of these papers do not know better than to give such frauds a hearing, and yet the editorial columns are constantly aiming to educate the people, to protect the real interests of the masses, and to expose wrong doing in every other line. Such advertising columns are constantly delivered up to calumnies against legitimate medicine, to the most shameful charge of ignorance of the ordinary family doctor, and the wonderful wisdom of the self-renowned vendor of a potent cureall. What would be the result if club committees should presume to criticise such a course on behalf of our best dailies, and what would be the effect if the banishment of such periodicals could be daily published in some rival paper? How few, indeed, could be found which could consistently publish such edifying news!

A SIGN OF THE TIMES.

THE amalgamation of the Bellevue Hospital Medical College with the Medical Department of the New York University, which has recently been announced, is an event of far greater significance than may, on first thought, appear. We are so unaccustomed to the spectacle of a medical college voluntarily renouncing its autonomous existence that, for a moment, we forget that it is merely a sign of the times. During the past decade New York has witnessed a marvellous transformation, which is now for the first time becoming fully apparent, in both medical teaching and medical colleges. In this time the three great medical colleges of the city have passed from the control of a few individuals who had gathered together and obtained a charter for granting medical degrees, and have become corporate parts of the two great universities of this city. The one to take the initiative in this step was the former College of Physicians and Surgeons. Shortly afterward the University Medical College, which for years had a bowing acquaintanceship with the University of the City of New York, so that the latter lent the former its mantle once a year at commencement, began coquetting in real earnest with the university, which had now taken a new lease of life, a new location, and a new name. This led, a short time ago, to the assimilation of the University Medical College by the New York University. In a very similar way Bellevue Hospital Medical College has, in the past, tried to "arrange" a union with Princeton and with Cornell universities, but there has always been some one to rise up and proclaim: "I forbid these banns."

It is probably not hazarding the truth to say that the motives that have prompted these private institutions in endeavoring to become an integral part of great public institutions were not by any means selfish ones. The owners of private institutions, such as all the medical colleges in this city have been

until very recently, have found it practically impossible to secure the slightest endowment, an absolute necessity for the existence of any large educational enterprise. To this there has been one illustrious exception in the shape of a gift to the College of Physicians and Surgeons, but the acceptation of the gift entailed such financial obligations that no private corporate body, such as it was then, could undertake to carry them. The consolidation with Columbia was the result. The other colleges were less fortunate in finding a philanthropist who would surround them with buildings which the moneys received from students would be insufficient to run. One of these colleges sought to strike the golden mean by getting just enough money to make it neither topheavy nor worth having by passing $100,000 from its right hand to its left. And while that hand held the rudder the sailing seemed fairly clear to uninterested lookers on.

To meet the exigencies of the present medical practice act of the State of New York, very different facilities are required than when the making of physicians was not sponsored by statutes. Institutions that had gone on for years putting the moneys obtained from students that remained after paying current expenses into the pockets of their respective "sevens," instead of into a sinking fund to provide for the rainy day which is now upon them in a sort of equinoctial storm, have found themselves face to face with the alternative of closing their doors or of attaching themselves to some endowed institution. Far-seeing men, who would rather commit their lusty youth to such a spouse than to take the chances of having the traditions of their institutions handed down to posterity by its alumni, have made their choice, and we believe wisely.

The union of the medical colleges of this city with the great universities points unerringly to the fact that the day of the private medical college enterprise is gone. The evolution, development, and dissolution of such colleges might be taken as a text to illustrate that the existence of such colleges is conditioned by their environment. In the past they have existed, and for a few years longer they may continue to exist in small cities and in country towns where the expense of running them is commensurate with the salary of a janitor, but in large cities their death knell was sounded a few years ago, and already the cortege is under way and proceeding with such momentum that nothing can stop it.

Advantage alone can accrue to the medical profession from such action as that taken by the Bellevue Hospital Medical College and the University Medical College. Both of these institutions have an honorable past. The former during the third of a century that it has been in existence has made for itself an enviable name. It has had the reputation of being a college in which the necessities for making a practical physician were taught. It has such repute not alone in this country but abroad, where it was one of the first to be recognized by the examining boards of the British universities. In joining hands and forces with its older rival, it will probably bring a leavening and virile influence that will make itself manifest in the character and the possessions of their combined offspring, future students.

We understand that the details of amalgamating the components of the two colleges, the faculties, have not yet been arranged. It is proposed, however, to have one single faculty, and this not necessarily selected from the membership of the two existing faculties, although naturally the links of the chain that formerly constituted the charmed circle stand a better chance of being forged into the new one than any raw metal. The difficulties of kneading the two faculties into a composite whole will probably be a considerable one, and the clashing of professorial individualities that have been on different sides of the fence in Twenty-sixth Street for a number of years may be attended by their mutual destruction, and then the men who are walking this city day and night with professorial ambitions partially or wholly concealed beneath their waistcoats may have a chance. In the mean time, however, their eyes are centred on University Heights, and they know not which way to turn.

EARLY EXPERIMENTS IN ORRHOTHERAPY.

It is a curious evidence of the slender results of empiricism and lucky hits in medicine, as in other sciences, that for nearly one hundred years vaccination remained the only example of serum therapy or pro phylaxis. Its employment was almost universal, but it remained alone of its kind, and its use was confined almost exclusively to the prevention of small-pox —yet not entirely, for good effects seemingly due to the action of the vaccine virus were noted by some keen observers in other affections.

One of these observers was Doctor, now Sir James A. Grant, of Ottawa. In a short article in the *Medical Times and Gazette* of March 14, 1863, the writer recorded some results which he had obtained in the treatment of certain dermatoses by vaccination. The first case was one of obstinate palmar psoriasis. After the unsuccessful employment of all the usual remedies, Dr. Grant resolved to make a trial of vaccination, "in order to observe the alterative effect of the vaccine virus upon the system, not without previous consideration, but with a firm conviction that under certain circumstances vaccine introduced into the system is one of the most powerful blood purifiers we possess. The operation was successfully performed, the pustule passing through the various stages from incubation to its separation. As it advanced from the third to the seventeenth day, the disease on the hands and fingers gradually receded, and on the twentieth day from the date of vaccination the parts recovered their natural appearance and continued so."

Three other cases of skin disease were reported, in all of which the eruption disappeared after vaccination. Arguing from the results obtained in these and other cases, Dr. Grant thought that vaccination should not be reserved solely as a means of protection against small-pox, but its employment should be "extended to the treatment of many cutaneous diseases . . . arising from irritant poison generated in the organism, or in that vital fluid, the blood." "Over such impuri-

ties," he added, "vaccination beyond a doubt possesses a powerful influence."

Vaccination has since been tried, with alleged success, in the prevention or treatment of other affections, notably in that of influenza by Dr. Goldschmidt, of Madeira. But whether it is actually curative in other affections, and, if so, whether the cure is effected by virtue of an antoxin, or because of a substitutive action, or perhaps through suggestion excited by the operation, we are not as yet in position to determine. Dr. Grant's cases, however they may be explained, are interesting as an early example of orrhotherapy other than in the prophylaxis of variola.

News of the Week.

Koch's Modified Tuberculin.—Recent advices from our Berlin correspondent announce the fact that Prof. Robert Koch has perfected tuberculin so that he is enabled to assure the profession that it now stands in the same relation to tuberculosis as a healing serum as antitoxin does to diphtheria. At least, such is his assertion in the recent issue of the *Deutsche medicinische Wochenschrift*.

A Physician's Gift to Education.—Dr. John C. Terrell, who practised medicine for many years in Roxboro, N. C., but who has spent the last few years of his life in Philadelphia, where he recently died, bequeathed $50,000 to the public schools of Person County, N. C., and in addition a sum sufficient to build a new school building in each of the twenty-nine townships of the county.

Medical College Consolidation.—At a special meeting of the State board of regents on April 8th, the proposition to consolidate the Bellevue Hospital Medical College and the New York University Medical School was considered and the consolidation was authorized. The name of the consolidated college will be the New York University-Bellevue Hospital Medical College. The faculty of the new college will number one hundred and sixteen, and there will be ample laboratory accommodation for the students in the Loomis and Carnegie laboratories.

The President's Physician, it is reported, will be Dr. Newton L. Bates, medical director of the navy, who will be stationed in Washington for the coming four years. President Cleveland's physician was Dr. Robert O'Reilly, of the army.

Driving Out a Healer.—A man has been drawing crowds recently in Providence, R. I., by claiming to be Schrader, the "divine healer," who was last heard of in Colorado, some time ago. But there is a medical practice law in Rhode Island, and, as Schrader had no license, the board of health forced him to leave. He then went to Worcester, Mass., and at once began blessing the people and treating their ailments. The man declares that he makes cures without pay, but his patients are made to understand that if they drop a dollar or two on the table the money will not be thrown into the street.

A Skiagraphical Medical Society.—It is proposed by those interested in the employment of the Roentgen rays in medicine to establish in London a society for the special study of this fascinating subject.

The Prince of Wales' Hospital Fund, in commemoration of the Queen's diamond jubilee, has been started by a subscription of £1,000 by Mr. W. W. Astor, formerly of New York.

An Unfortunate Mistake was committed by the County Medical Society's agent in arresting a reputable registered physician last week under the impression that he was practising without a diploma. The society has done such good work in protecting the interests of the profession that we trust the doctor will forgive its misdirected zeal.

Chicago Colleges of Medicine should now follow the example set in New York and double up. There are nineteen, which would just make nine and one to spare, or another could be founded at once, to make out a round ten, and this surely ought to be enough for the next two or three years.

The British Medical Association Meeting.—The arrangements for the sixty-fifth annual meeting of the British Medical Association, to be held in Montreal at the end of August and the beginning of September, are now almost completed, and the preliminary programme is being distributed to the members. The proceedings will begin on August 31st by the installation of the president-elect, Dr. Roddick, who will then deliver his presidential address, the subject of which will be "Medical Education in Canada." On the afternoons of September 1st, 2d, and 3d, general addresses will be delivered in the Windsor Hall; they will be of a more or less popular character, and will be open to the public. The address in medicine, as we announced some weeks ago, will be delivered by Dr. W. Osler, of the Johns Hopkins University; that in surgery by Mr. William Mitchell Banks, surgeon to the Liverpool Royal Infirmary. The reader of the third address will, it is said, be a Frenchman; but, as the gentleman first invited declined because of a previous engagement at Moscow, another had to be selected, and his name cannot be announced until his acceptance has been received. The meetings of the sections will be held from 9:30 to 1 o'clock on the morning of each day. The following are the chairmen of the various sections: Medicine, Dr. Stephen Mackenzie; surgery, Mr. Christopher Heath; obstetrics and gynæcology, Dr. W. J. Sinclair; psychology, Dr. R. M. Buche; anatomy and physiology, Dr. Augustus Weller; pathology and bacteriology, Mr. Watson Cheyne; ophthalmology, Dr. E. Nettleship; pharmacology and therapeutics, Dr. D. J. Leech; laryngology and otology, Dr. Greville Macdonald; dermatology, Mr. Malcolm Morris.

A Vivisection Bill has been introduced into the Michigan legislature, which is free from many of the objections which similar measures to regulate experimentation on animals often contain. It provides that persons desiring to experiment upon animals must first

obtain a permit from the secretary of State, which will not be granted except upon the person furnishing proof of justifiable intent. No experiments of a painful nature can be made unless the animal is anæsthetized. Other provisions of the bill look to the inspection of laboratories and other places where vivisection is carried on.

Small-pox.—There have been found seventeen cases of small-pox in this city since March 1st last. In consequence of this, the staff of the bureau of contagious diseases has been temporarily increased by the appointment of fifteen new inspectors. Some of these have been assigned to inspection duty; others are held in reserve in the office to attend promptly any case in which symptoms of small-pox are reported. In every case of small-pox reported, inspectors are at once sent to vaccinate the persons living on the four sides of that block, and also the four sides of the adjoining block.

Definition of a Medical Charity.—Dr. Campbell Black, of Glasgow, has a way of speaking out in meeting that is distressing to some of his colleagues. He has recently been talking about the dispensary abuse, and says that the "end and aim of a medical charity is to make consulting physicians and surgeons, and it is for this purpose nowadays that all hospitals, great and small, special and general, exist."

A New Hospital in London.—The Hebrews in London propose to celebrate the sixtieth year of the Queen's reign by erecting and endowing a home and hospital at Tottenham for Jewish incurables. A site of about four acres has been acquired, and accommodation will be provided for fifty patients.

The Objectionable Features in the New Charter.—Dr. George B. Fowler, health commissioner, writes: "Among the criticisms of the new charter, none has been more severe than that directed against Sections 1,247 and 1,249, relating to the duties of physicians in reporting cases of contagious and infectious disease. These sections are referred to as if they were entirely new and unprecedented and designed to give the health department a dangerous and tyrannical authority over the members of the medical profession. Now the fact is that these sections are not new. They constitute Sections 608–610 of the Consolidation Act of 1882, under which the city has been governed for fifteen years, and were originally passed forty-seven years ago, Sections 1,247 and 1,249 being in Chapter 275, Laws of 1850, and Section 1,248 in Chapter 384, Laws of 1851." [The mere fact that a thing is very old does not necessarily prove that it is very good.—Ed.]

Jubilee Exercises of the American Medical Association.—The committee of arrangements has set aside an hour on the second day of the meeting for exercises to commemorate the founding of the association in Philadelphia in 1847. The founders of the association believed that it would raise the standard of medical education and combine the medical profession of the United States in one body, and the committee has taken steps to secure the presence upon the stage with Dr. Davis of the presidents of the State medical societies and of the State boards of medical examiners, as an exhibit showing the success attained through the instrumentality of the association. In addition to an address by Dr. Davis, there will be two or three other short addresses to add to the interest of the occasion. Of the original members of the association, there are still living, the committee states, Dr. N. S. Davis, of Chicago; Dr. Alfred Stillé, of Philadelphia; Dr. John B. Johnson, of St. Louis; and Dr. David F. Atwater, of Springfield, Mass.; and the committee hopes that these gentlemen will all be present to take part in the meeting.

Obituary Notes.—Dr. Charles Hammer, aged sixty-five years, died at his home in Schenectady, April 8th, of apoplexy. Dr. Hammer was formerly president of the County Medical Association. He was a native of Germany, and came to this country in 1854 and settled in Schenectady in 1867.—Dr. Sherman Street died at Arkville, N. Y., Friday, April 2, 1897, aged ninety-four years. He began the practice of medicine at Roxbury, N. Y., about 1840, having received a degree from the University of Vermont. Shortly before the anti-rent troubles he removed to Arkville, where he practised until within a few years of his death.—Dr. Thomas S. Dawes died on April 11th, at his home in Saugerties, N. Y., of apoplexy. He was born in Massachusetts in 1822, and was graduated from the Albany Medical College in 1848. He had practised medicine in Saugerties for forty-five years. He was at one time president of the Ulster County Medical Society, was a member of the New York State Medical Society, of the American Public Health Association, and an honorary member of the Berkshire County (Mass.) Medical Society. He was for six years a member of the State board of health.—Dr. C. R. Wiley died at Vineland, N. J., of pneumonia, on April 2d, at the age of fifty-three years. He was president of the South Jersey pension examining board and consulting physician to the New Jersey Training-School for Feeble-Minded Children.—Dr. Hugo Engel died of pneumonia, at Philadelphia, on April 5th, at the age of fifty-three years. He was a native of Berlin, and began the study of medicine in Germany, graduating from Jefferson Medical College in 1874. Subsequently he became chief clinical assistant in the out-patient medical department of Jefferson Hospital, and later professor of therapeutics and nervous diseases in the Medico-Chirurgical College. He translated Da Costa's "Diagnosis" into German.—Dr. Edson Sewell Bastin, professor of materia medica and botany in the Philadelphia College of Pharmacy, died on April 6th, of cerebral hemorrhage, at the age of fifty-four years.—Dr. Leverett Silliman Kelsey died of pulmonary tuberculosis, at Mount Vernon, Ohio, April 9, 1897. He was born September 4, 1854; graduated at the Medical College of Ohio, 1879; was resident physician of the Hospital of the Good Samaritan until March, 1880. In 1882 he took a degree at the Bellevue Hospital Medical College, New York. He subsequently practised medicine for fifteen years with great success at Richmond, Ind.

Leprosy is said to be spreading in Spain in a somewhat alarming manner. In the village of Alcublas, near Valencia, more than a dozen families are said to be affected.

The Notification of Tuberculosis. — Commenting upon the New York health department's action in regard to the notification of tuberculosis, *The Hospital* says that "it is impossible to shut one's eyes to the fact that this is the direction in which many other sanitary authorities are now drifting, and that the notification and the State control of consumption may before long become burning questions. Those, however, who have studied the causes of tuberculosis will recognize how shallow is the pathology of those who profess to be able to stop its ravages by notification, and other like measures for the muzzling of the microbe. The first and the main thing that has to be understood is that consumption, when it permeates a community, is not merely the result of the scattering of the infection, but is the outcome of, and perhaps one might not unfitly call it the punishment for, certain well-known sanitary sins. We may, therefore, be allowed to doubt whether any sanitary administration will ever be able by aid of notification to absolve us from the consequences of our misdirected civilization."

Medicine and Politics.—The interesting announcement is made that the authorities of Schuylkill County, Pa., have decided to take "out of politics" the appointments for the new $50,000 hospital erected at Pottsville in connection with the almshouse, "in order to ensure more efficient service."

Typhoid at Mount Sinai.—The Mount Sinai Hospital management is congratulating itself that the typhoid epidemic, which has lasted for three months, is now over. There have been in all twenty cases—the superintendent, seventeen nurses, one maid, and the elevator boy. One case terminated fatally.

A Second Nurse in the Bellevue Dispensary.—An additional nurse has been appointed to the staff of the Bellevue Dispensary. This permits one nurse to devote her entire attention to the gynæcological while the other is engaged with the surgical work.

The Good Samaritan Dispensary.—The sixth annual report of this institution, just received, shows that while over 10,000 more visits were paid by patients, the number of actual patients was more than 100 less than in the preceding year: 3,000 fewer prescriptions were given, and almost $3,000 was saved in expenses. During the past week this institution has carried out a competitive examination for the position of attending surgeon for skin diseases. We understand that in spite of the fact that there is a salary attached to the position, it was competed for by a number of well-known men. The Good Samaritan deserves to secure the services of excellent men, and it usually has succeeded in doing so. The service is large and good; the patients, with a few exceptions, are of a class requiring medical aid; the building is one of the finest in the country; and, above all, its theory that the physician who does the work should be compensated is an object lesson which other institutions might well follow.

A Falling Off in Medical Students.—The number of medical students in Missouri is reported by the *Kansas City Medical Record* to have decreased over sixty per cent. this year, and yet St. Louis heads the list of cities as regards the number of her medical schools.

Information Exchanged.—Dr. Merideth, on leaving his office to attend a patient, wrote on the slate on his desk: "Will be back at eleven o'clock." When the doctor returned he found this under his notice: "Will not be back at all. Burglar." A number of small articles were found missing from the office.

An Antivivisectionist Statement.—A Mr. Coleridge, an officer of a London antivivisection society, has published a letter, written by him to the Prince of Wales, asking that the hospital fund to commemorate the Queen's diamond jubilee may be so distributed that none of it may go to any hospital in whose school any experiments are made on animals. The writer insults the prince's intelligence by informing him, and apparently expecting him to believe, that there are laboratories, attached to several of the hospitals in London, where "hapless dumb animals, daily and hourly, are slowly cut up alive without even the pretence of anæsthetics."

The First Ovariotomist.—An attempt having recently been made to deprive Dr. McDowell of the honor of having performed the first ovariotomy and to transfer it to Robert Houston, of Glasgow, Mr. Greig Smith has resifted the evidence in an article in the *Practitioner* for March, and decides without hesitation for McDowell. Houston, he says, believed that ovarian cyst was a simple dropsy of the ovary, and was to be treated by tapping, or, if there were secondary cysts, by incision. His case was one of incision, and he clearly describes it as such. No one of his contemporaries says it is anything more than incision. One of them, indeed (Donald Monro, in his 'Treatise on the Dropsy,' second edition, London, 1756), definitely claimed it as such, and uses its success as an argument against extirpation." But although not an ovariotomy, Houston's was, he says, a bold position, and for such he deserves great credit. To him is also due the honor of having been the first to suggest operation for extra-uterine fœtation.

The French Congress of Alienists and Neurologists will be held this year at Toulouse, on August 2d and following days. The questions proposed for discussion are: 1, The diagnosis of general paralysis; 2, infantile hysteria; 3, the organization of the medical service in lunatic asylums.

A Label for Doctors.—The Russian government has decided to label medical men by means of a silver shield, one inch wide by one and one-half inches long, having a raised design of two intertwined serpents. This is to be worn conspicuously on the breast, and it is hoped that it will prevent the killing of the doctors by excited peasants, a practice that they frequently

indulge in during epidemics of cholera and other especially fatal diseases.

The Population of France in 1895, according to statistics recently published, was less by nearly 17,000 than it was the year before. The falling off is manifestly due to the decreasing birth rate, which since 1890 has been below the death rate. A comparison of the statistics by decades during the present century shows a progressive decrease. During the years 1801–10 there were 33 births per 1,000 inhabitants, and this rate has declined with each decade to 32, 31, 29, 27, 26, 26, 25, and 24; during the first half of the last decade (from 1891–95) the rate has been 22 births per 1,000 of the population. Such statistics would seem to justify the fear, so widely felt, that France is doomed to become extinct as a nation.

"Treatment" is the name of a new journal, the first number of which was published in London on March 11th. As its name implies, it will be devoted chiefly to practical therapeutics, yet it will admit articles having a direct bearing upon diagnosis or prognosis as well as those dealing solely with treatment. It will be divided into four parts, each with a chief editor and a staff of assistants, and each part will appear six times a year. We notice in the first number an abstract of an article on the bicycle treatment of scoliosis by Dr. Kiliani, which appeared originally in the MEDICAL RECORD of October 31, 1896, but which is here credited to an English annual.

The Medical Society of London has elected to honorary membership Dr. T. G. Roddick and Sir W. H. Hingston, of Montreal.

Another Case of Small-Pox was discovered a few days ago in the New York Hospital, the disease having evidently been acquired from a patient who had been taken into the hospital about two weeks previously through a mistake in diagnosis.

To Prevent the Clouding of Laryngoscopes.—An ingenious device to prevent the clouding of dental mirrors, which is, of course, equally applicable to the mirrors used in nose and throat work, has been made known by an English dentist, Mr. George Wallis. This consists simply in smearing the surface of the mirror with soap and then polishing it with a dry cloth. If this is done, the troublesome warming of the laryngoscope over a lamp is entirely unnecessary. This method has long been used by housewives for polishing mirrors, but we do not know of it ever having been employed by laryngologists.

Navy Department.—Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending April 3, 1897: March 27th.—Surgeon C. U. Gravatt ordered to examination for promotion, Washington, D. C., April 5th. March 29th.—Assistant Surgeon J. C. Prior ordered to the naval laboratory, New York, and department of instruction, April 5th; Assistant Surgeon F. C. Cooke ordered to examination for promotion, New York, April 5th; Assistant Surgeon G. D. Costigan detached from the *Vermont*, April 6th, and ordered to the *Lancaster* per steamer of April 7th. April 2d.—Assistant Surgeon D. H. Morgan, detached from the naval laboratory, New York, April 6th, and ordered to the Naval Academy, April 8th.

Deaths from Chloroform in Great Britain during January and February of the present year numbered twelve, as against seven for the first two months in 1896. During the first two weeks in March eight more deaths occurred.

The Colored Home and Hospital of this city has sold its property on First Avenue and will move farther up town. The present site has been occupied by the hospital since 1848.

A Filthy Water Supply.—According to the *Times-Herald*, the water supplied by the city of Chicago is so bad that the health department has uttered the warning that not even boiled water is safe to use. Heavy rains and stirring up of the water by high winds have so befouled the lake about the cribs that the city pipes are filled with diluted sewage.

The Medical and Chirurgical Faculty of Maryland.—The annual meeting of the State Society of Maryland will be held in Baltimore, at the Faculty Hall, on Tuesday, Wednesday, Thursday, and Friday, April 27th to 30th inclusive. On Tuesday evening there will be the annual discussion, the subject selected being "Peritonitis."

A Dead-Body Trust.—These are troublous times for trusts, and the latest to come to grief is a pool of Cleveland medical colleges for the distribution of subjects for dissection. According to the *Leader* of that city, the Cleveland University of Medicine and Surgery has formally withdrawn from the trust on account of alleged unfair treatment on the part of the other colleges, it having received only two bodies when it asked for twenty. This leaves the Western Reserve University Medical College, the Cleveland Medical College, and the Ohio Wesleyan Medical College in the pool. These colleges, the *Leader* says, are making strenuous efforts to induce the Cleveland University of Medicine and Surgery to return to the fold, but so far have met only with cold rebuffs. The latter institution promises a lively competition for the pool. It has already beaten the pool in making application for two bodies in charge of Coroner Arbuckle.

The American Medico-Psychological Association will meet in Baltimore on May 11th, 12th, 13th, and 14th. During this time the Maryland State Insane Asylum, generally known as "Spring Grove," will celebrate the one hundredth anniversary of its foundation. It is interesting to note that Doctor Richard Sprigg Steuart, who did so much for this asylum during his lifetime, was the one who suggested the present site of the Johns Hopkins Hospital.

The Baltimore City Council is considering the advisability of reducing the annual appropriations to hospitals and charitable institutions by establishing an institution for the care of waifs and the indigent sick; also establishing a drug store in each ward in the place of supporting dispensaries.

Clinical Department.

A CASE OF CEREBRAL SYPHILIS WITH TYPHOID FEVER SUPERVENING.

By J. M. O'NEILL, M.D.,

BUFFALO, N. Y.

I HAVE lately had a case under my care which is within my own experience unique. My patient, a man of about thirty years of age, had been suffering from a syphilis of long standing. He first contracted the disease some five years ago, at which time he was under my treatment for a period of five weeks; he then, by the advice of friends, underwent the Hot Springs treatment. From the time when I first attended him I did not again see him until the 25th of October last, when I was called in and found him suffering from most of the symptoms of syphilis in the tertiary stage—he had hemiplegia of the left side, gummatous growths, lesions, etc. I administered large doses of bichloride of mercury, producing salivation, at the same time giving him moderate doses of iodide of potassium, and until the latter part of January he appeared to be progressing as well as under the circumstances could have been expected, when he developed symptoms which for a short time somewhat puzzled me. The symptoms were those of typhoid, but not thinking that in his condition such an attack was likely, and knowing that some authorities—notably Huebner—have recognized a typhoid stage as occurring sometimes in cerebral syphilis, I did not at once diagnose the case as one of typhoid. However, as the symptoms continued and grew more acute—diarrhœa, sordes, delirium, and a very obstinate hiccough—I made an examination and found on his abdomen typhoid patches well defined, and in all respects there could be no doubt that it was a case of true typhoid. The patient lingered for about a week in this state, and died.

The feature of this case which struck me as abnormal, and to which I wish to draw attention, is that a person whose system at the time was saturated with mercury should have been the victim of typhoid. One would imagine that he should have been in such an aseptic state that he ought to have been proof against the germ of typhoid.

PUERPERAL CONVULSIONS.

By FRANCIS W. GALLAGHER, M.D.,

EL PASO, TEXAS.

MUCH has been written of late in favor of operative interference with the contents of the womb and against bloodletting in the treatment of eclampsia. The experience, except of a few physicians, includes but a small number of cases. As a rule, puerperal convulsions are not classified, for purposes of comparison, into ante-partum and post-partum varieties. This division is exceedingly important when considering statistics, as post-partum eclampsia is much less fatal than are convulsions preceding labor. For this reason the percentages of mortality vary within very wide range.

Dr. George Van Schaick, of New York, says, in the New York *Therapeutic Review*, that while some authors claim as low as fourteen per cent. of mortality only, his personal inquiry among five physicians with large obstetrical experience revealed a death rate of eighty per cent., and that further inquiry of two experienced nurses had shown that together they had seen nine cases without a single recovery. No intelligent or valuable deductions can be drawn from any treatment when it is not explicitly stated whether or not the convulsions preceded or followed labor. Contrary to what, from the journal reports, one would judge to be the American practice, the French obstetricians—among others Tarnier and Charpentier—strongly advocate non-interference with the contents of the womb (except when labor begins spontaneously) and bleeding, as affording the best results for the safety of the mother.

My experience includes but six cases of ante-partum eclampsia, and of these but four are available in considering therapeutic measures. These four strongly indorse the value of non-interference with the progress of labor and the value of bloodletting as means of treatment.

CASE I.—A multipara. I was called in consultation on a Wednesday morning, after her second convulsion. The patient was comatose from the time of her attack. She was bled, and next day was conscious and apparently doing well. I know nothing of the subsequent treatment. The patient did not have another convulsion, but died on the following Monday morning.

CASE II.—Also a multipara. She was bled twice within three hours, and subsequently treated with hypodermic injections of chloral. This patient had had fourteen convulsive seizures, and was in profound coma when first seen. She made a good recovery.

CASE III.—A primipara. This patient was not seen for some hours after her first seizure. During this interval she had a number of convulsions, and all of this time she was in deep coma. She was bled, and convulsive manifestations were controlled for some hours by inhalations of chloroform from time to time. Hypodermic injections of chloral were also given. This patient also recovered.

CASE IV.—A primipara. This patient, like the two preceding, lived a long distance in the country, and had been in convulsions and coma for some hours when seen. She, like the others, was bled and was given chloral hypodermically, and also recovered.

To analyze briefly the foregoing: The first patient lived several days after her last convulsion, and the cause of death is not known. However, the length of life after the last convulsion demonstrates, I believe, the value of bloodletting. The recovery of the other three patients is further demonstration of the value of the treatment.

May not the more favorable statistics of post-partum eclampsia be due to the loss of blood accompanying labor?

BULLET LOCATED IN THE MOTOR AREA OF THE BRAIN WITH *X*-RAYS.

By PHILIP D. BUNCE, M.D.,

HARTFORD, CONN.

A. B——, sixteen years old, was accidentally shot, October, 1895. A 22-calibre bullet from the ordinary breech-cap cartridge entered the skull through his left nostril, with hardly any external wound.

The patient's own account is unreliable, as his mental condition has deteriorated since the accident. He says his left leg became powerless at once, but that his arms and face were all right.

Immediately after the accident and for several days he was semiconscious. On leaving the hospital he had paralysis of the face, arm, and leg on the left side, and had to use a cane.

December 17, 1896, no paralysis of face; paralysis of left arm, with contractures and some atrophy. Left knee jerk very much exaggerated, but he can walk rapidly, in spite of pronounced toe drop, without any cane.

By means of the *x*-ray apparatus the bullet was distinctly located with the fluoroscope. No exact

measurements were made, but the bullet seemed to be located about the upper third of the fissure of Rolando on the right side.

The Crookes tube used in this case differs from that in ordinary use, in having an auxiliary bulb which increases the power of the *x*-rays very much. It was necessary to use a strong current, together with storage batteries, before a satisfactory result could be obtained. Two unsuccessful attempts were made to get a photograph, with an exposure in both cases of one hour.

Considerable trouble has been experienced since the tests, from the hair coming out on that side of the head nearest to the Crookes tube. Also considerable dermatitis is present over the same area.

Operation was not advised, as it was thought the destructive changes in the brain were permanent.

13 Pratt Street.

CASE OF CONGENITAL AFFECTION OF THE HEART IN A WOMAN TWENTY-SIX YEARS OLD.[1]

By CHARLES E. NAMMACK, M.D.,

Assistant Visiting Physician to Bellevue Hospital, New York.

Sarah J——, twenty-six years old, native of United States, has been a patient of this hospital several times. She has been told by her parents that she was a blue baby. According to her own recollection she has passed safely through measles, mumps, chicken pox, pneumonia, pleurisy, and three years ago twice vomited a large amount of blood. To the writer's knowledge she went through the course of a moderately severe bronchitis in October, 1896, without any uncommon symptoms other than marked irregularity of the heart's action and a deepening of her habitual cyanosis. Her family history throws no light on the etiology of her present condition. She is emotional in temperament, and given to that morbid introspection and self-analysis which pertain to subjects long resident in hospitals.

The symptomatology of her case is as follows: Cyanosis, which is increased by the most trivial disturbing influences and which is most marked in the visage, especially upon the mucous surfaces. Her stature is stunted and puny. The tips of the fingers are bulbous and the nails incurvated. Her bodily temperature has never been charted as less than 97.2 F., but fluctuates from slight disturbing causes. Menstruation is regularly performed at present, but periods of amenorrhœa have occurred since puberty. While in bed her pulse ranges from 52 to 80, and her respirations seldom fall below 20. Precordial pain is not a common complaint, but she frequently suffers from headaches and various neuralgiæ. There is no record of mucous hemorrhages other than the two attacks of hæmatemesis mentioned by herself. She is disqualified for the active duties of life, but assists in the ward work to the extent of her ability. Thus far, intercurrent diseases have not been badly tolerated. There are no signs of pulmonary tuberculosis.

Opinions as to the exact anatomical changes in this case have been almost as varied as observers have been numerous. It seems tolerably certain, however, that the following lesions exist: First, stenosis at the pulmonary orifice, as shown by hypertrophy of the right ventricle with dulness extending beyond the right border of the sternum, diffused cardiac impulse, thrill, and systolic murmur in the second intercostal space on left side; second, imperfection of the interventricular septum, indicated by a loud systolic murmur, heard with greatest intensity near the apex and transmitted to the axilla and back and not transmitted to the vessels, with obscuration of the first sound; third, a patulous condition of the ductus arteriosus, manifested by murmur over the upper part of the sternum and accentuation of the second pulmonic sound.

The limits of this paper preclude any discussion of the theories of the etiology of cyanosis in these cases, as this is still unsettled ground. The prognosis as regards duration of life is better in this case than in any other form of congenital heart defect of serious character. Sixteen per cent. survive the twentieth year and one individual reached the age of fifty-seven (Barton Cooke Hirst).

Our patient receives no special medicinal treatment except to meet temporary indications. Hygienic management, especially protection from cold and physical exertion, is so beneficial that she spends but little time each year out of the hospital.

42 East Twenty-Ninth Street.

[1] Patient presented before the New York Academy of Medicine, section on pædiatrics, March 11, 1897.

CHRONIC DIPHTHERIA.

By JOHN H. MOORE, M.D.,

Bridgeton, N. J.

Chronic diphtheria is rare. Mackenzie has cited a case in which the membrane persisted in reforming for three months. Other cases are reported by Isambert, Barthez, and Heybre. (See "Reference Handbook of the Medical Sciences," vol. ii., p. 470.)

The following case, reported in detail, cannot therefore but prove of interest. A. H. L——, aged five years, a healthy, robust child, though subject to attacks of tonsillar inflammation, was taken with the usual symptoms of diphtheria, December 30, 1896. In my first examination of the child the tonsils were found uniformly swollen and dotted with points of exudation, while the entire pharyngeal mucous membrane was the seat of catarrhal inflammation. The clinical features were those of acute follicular tonsillitis. There was no evidence of constitutional involvement.

In view of the fact that the child had been exposed a few days before to possible contagion of diphtheria, he was isolated and his case was carefully watched. He was treated with a mixture of tincture of chloride of iron and glycerin. The throat cleared in three days and the child appeared entirely well. On January 3, 1897, slight hoarseness appeared, which on the following day increased to complete aphonia, with a strong tendency to laryngeal stenosis. I promptly injected two thousand units of antitoxin, and in view of the increasing obstruction to respiration advised early intubation. This was done at night of the same day by Dr. Edwin Rosenthal, of Philadelphia. At the same time the second dose of two thousand units of antitoxin was given. The patient was at once relieved and fell into a restful sleep. He soon began to expectorate large quantities of shreds of membrane, which apparently gave permanent relief. During the three days following there was a steady improvement in the constitutional condition.

On January 7th, the membrane reappeared in the larynx. Two thousand units of antitoxin were injected, followed in several hours by another injection of one thousand units. The tube, which had been replaced, was coughed up, yet within twelve hours all the symptoms were greatly ameliorated and the patient was apparently on the high road to recovery. Up to the 10th of the month he seemed entirely well, the throat being free from membrane. On the following day, however, he began to be dull and apathetic, and a patch of membrane was seen forming upon the soft palate. I promptly injected fifteen hundred units of antitoxin and at night gave another injection of one thousand units. Within twelve hours after the first

injection of antitoxin there was great improvement. The lassitude had disappeared and the appetite returned. Improvement continued till January 16th, when another relapse occurred, preceded by the same symptoms as before. This time the membrane occupied a much more extended surface, involving nearly the entire pharyngeal mucous membrane and the posterior nares. I made a local application of corrosive sublimate, 1 to 5,000 solution, and followed up with systematic application of Loeffler's solution No. 2. Antitoxin was again injected, the dose being one thousand units, which was repeated in five hours. Repeated bacteriological tests showed the presence of the bacilli diphtheriæ, but why they persisted in reasserting themselves and why the antitoxin failed to produce the characteristic immunity to the disease were the points of special interest.

During all this time I had used mercury freely, either in the form of the mild chloride or the bichloride, as adjunct to the treatment. Noting that some clinical observers have found reasons to believe that the constitutional effects of mercury are antagonistic to antitoxin, I determined to discontinue the mercury and depend wholly upon antitoxin, and, if possible, keep up a condition of immunization by regular and systematic repetition of the dose. In accordance with this plan I administered antitoxin in five-hundred-unit doses night and morning, and continued for five days, when, there being no further indications for treatment, it was discontinued. There was no relapse and the progress to complete recovery was speedy and entirely uneventful.

The prominent features of the case are the persistent tendency to relapse, the relapse always being a new infection and the point of infection probably chronic ulcers, and the prompt response of the disease to antitoxin, as shown by the early amelioration of all the symptoms and the disappearance of the membrane. No injurious or untoward effects, either general or local, were noted from the frequent and repeated injections of antitoxin. During the entire period of illness the child received sixteen thousand five hundred units of concentrated antitoxin.

As regards the effect of the administration of the antitoxin upon the temperature of the child, each injection was followed by a slight rise, which soon subsided. During the progress of the disease the temperature was several times found to be subnormal for a few hours' duration, a temperature as low as 95° F. being recorded. There is no doubt that in this case intubation prolonged life till the antitoxin could produce its effects, and that in the selection of antitoxin that product which represents the largest number of immunizing units in the same quantity of serum is to be preferred, since this reduces to a minimum the possible globucidal action upon the blood and the tendency to excite urticaria.

ABSCESS OF THE MASTOID, EXTENDING ALONG THE COURSE OF THE LATERAL SINUS.

By WILLIAM G. E. FLANDERS, M.D.,

ATTENDING SURGEON AT THE HÔTEL DIEU, BURLINGTON, N. J.

This case is one that shows how extensively bone may be diseased in the mastoid region, without local symptoms, and also that pus may actually come in contact with the dura without causing grave constitutional symptoms.

Mrs. S. H——, called at my office December 17th, complaining of deafness in the right ear which had followed an attack of influenza, from which she had partially recovered. I examined her with the following results: B. C., normal; A. C., R. E., $\frac{3}{40}$; L. E., $\frac{3}{40}$. Spoken voice could be heard at six feet with R. E. The external auditory canal was normal; the membrana tympani was contracted and there was a slight tinge of redness about the centre; there was complete absence of tenderness about the canal, the external ear, and the mastoid process. The temperature was normal. The ear was syringed out with hot boric-acid solution, and the throat, nose, and nasopharynx were cleared out with the normal salt and Dobell's solution. The patient was directed to use the hot boric-acid wash for the ear twice daily. She returned in two days, feeling much better. Hearing was $\frac{6}{40}$ in the affected ear. There was no indication of middle-ear disease. Practically the same treatment was given as on the previous visit. On the 20th she sent word that she was well except for a slight discharge from the external auditory canal. The 22d she came into the office complaining of pressure and unnatural heaviness about the head. The angle of the mouth was drawn to the left and the lower lid of the right eye drooped, and it was impossible to close it. There was a slight discharge of pus from the external auditory canal of the right side; the membrana tympani was perforated in the upper posterior quadrant, and pus was oozing through this opening. Temperature was normal. She was sent home and put to bed on a light diet. The ice coil was applied over the mastoid process; cathartics were given, etc. The discharge from the auditory canal was quite free at this time.

The 23d she was much improved as to her general condition, but the paralysis remained about the same. She continued comfortable, but on the morning of the 25th the paralysis had increased and I advised immediate operation. At 3:30 P.M. I operated, assisted by Dr. William B. Lund. After the parts were thoroughly shaven and prepared, I made the usual incision and exposed the mastoid process. After denuding it of its periosteum, I removed with a half-inch trephine a button of bone over the antrum, also exposing a part of the lateral sinus. When this was removed, I found quite a quantity of pus, the cells being broken down and forming a general pus cavity. With mallet and chisel I removed all of the bone between the opening and the tympanic cavity. I then discovered that the pus had burrowed along the course of the lateral sinus for a distance of about two inches. It had separated the membrane for its entire depth and about one inch in width. The bone was removed along this pocket by the rongeur. As there was such a large amount of pus in the tympanic cavity and the ossicles were evidently diseased, I removed them together with the drum membrane. We then had a free passage from the external auditory canal out through the opening in the mastoid process. The wound was washed thoroughly with normal salt solution and the greater part of the incision over the mastoid was closed with silkworm-gut sutures. The wound was packed with iodoform gauze and dressed with a large covering of sterilized gauze. The patient rallied from the anæsthetic without shock. At 10 P.M. she had a temperature of 99.2° F., which was the only time that it was above normal. She made an uninterrupted recovery and at the end of four weeks she was able to resume her household and social duties.

This case adds one more to the list of those that have been reported, showing that external signs of inflammation and tenderness upon pressure are not safe guides as to the condition of the mastoid cells.

Early Motion in Fracture of Lower Limbs.—Allowing the patient to walk around at an early date lessens the duration of time required for cure and the chance of muscular atrophy.—BARDELEBEN.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PÆDIATRICS.

Stated Meeting, April 8, 1897.

J. H. FRUITNIGHT, M.D., CHAIRMAN.

Exophthalmic Goitre Treated with Thymus Gland.—DR. CHARLES E. NAMMACK presented a girl, twenty-one years of age, who had applied for treatment for palpitation of the heart, prominence of the eyes, and swelling in the neck, symptoms which had first been observed ten years ago. To-day all three symptoms were marked, but were less striking than before the use of thymus gland, which was begun two months ago. The pulse rate was 144, and among the symptoms were anæmia, mental depression, frequent attacks of profuse perspiration, tremor, transient albuminuria, nocturnal incontinence, dyspnœa. Among the theories regarding the etiology of exophthalmic goitre was that which attributed it to perverted function of the thyroid gland, and to counteract such influence some had removed the gland, some had administered thyroid extract, and in both instances the method had received both praise and condemnation. Later thymus gland was administered, and the result had been summed up by Mackenzie that the action when beneficial was probably due to a nutritional influence, such as cod-liver oil exerted in certain conditions, and not to any specific action. In the present case Dr. Nammack had begun by giving a three-grain thymus tabloid, said to be equal to eight grains of the gland, and had increased the amount to nine tabloids, equal to seventy-two grains of the gland. The patient claimed to have received greater benefit from this treatment than from any other—the nervous symptoms and palpitation were less, the nutrition was better, the exophthalmus less; it was more difficult to judge of any variation in the size of the goitre.

DR. A. D. ROCKWELL discussed the treatment of exophthalmic goitre. He had seen about sixty cases altogether, and the treatment had been chiefly dietetic and hygienic and the use of electricity. Some had not been improved, but the majority were markedly benefited. He employed galvanism, using large clay electrodes, which enabled him to give from fifty to one hundred milliamperes. One author had claimed that the benefit was through a mechanical effect of the current on the thyroid.

DR. H. L. TAYLOR asked about the influence of diminished chest expansion, as pointed out by Dr. Bryson, and Dr. Nammack replied that the later review of the subject by Patrick, of Chicago, would show, according to that gentleman's view, that the diminished chest expansion was not a cause but a result of the deficient muscular power accompanying the disease.

Congenital Stiffness of the Shoulder and Elbow Joints of Both Arms.—DR. HENRY LING TAYLOR presented the patient, a child seventeen months old, who was first seen by him when six weeks old. At that time there were stiffness, sembling ankylosis, at the shoulder and elbow joints, and to some extent in the wrists and fingers. The mother stated that the doctor put the left arm up in splints for two weeks after birth for dislocation of the shoulder. While Dr. Taylor found greater stiffness in the left limb, there was considerable also in the right. A neurologist had made the diagnosis of birth palsy from injury to the brachial plexus, but Dr. Taylor thought this would not account for stiffness of the joints. There were no other signs of malformation.

DR. MARY PUTNAM JACOBI thought the skiagraphs passed around gave evidence of incomplete formation of the joints, and it was her impression that the articular surfaces had not been as fully formed as usual, not in proportion to the development of the shaft of the bones; hence the imperfect joint function.

DR. R. H. SAYRE thought the skiagraph showed a larger space than normal between the radius and the articulation at the elbow, whereas the end of the ulna had some appearance of having slid up somewhat on the humerus, and that the first step toward obtaining motion would be to make traction and bring the ulna down.

DR. GALLANT inquired whether there had been asphyxiation at birth and efforts to revive the child. He made the inquiry because observations under Dr. Van Arsdale at the Good Samaritan Dispensary had shown that efforts at resuscitating children by lifting them by the hands, or other movements, and of dragging children by the hand, as mothers did when passing over curbstones, were not infrequently followed by stiffness at the elbow and helplessness of the hand. If the case were in an infant, it would make no attempt to raise or use the arm, which hung at the side. There had been seen at the dispensary about seven hundred and fifty cases of subluxation at the elbow-joint in children from two to ten years of age.

The mother replied that the child had to be resuscitated when born.

Congenital Dislocation of the Shoulder-Joint.—DR. F. TILDEN BROWN presented the case because it was related to the subject of the paper which Dr. Phelps read later. The diagnosis was not always made between congenital dislocation and obstetric palsy of Erb. Both accidents might occur from the same cause, efforts at delivery made by the obstetrician. In the case presented the mother had sustained great nervous shock when the infant was five months old, and from that date no longer experienced fœtal movements. Delivery took place at term, without aid, the labor lasting thirty-six hours. It was noticed within at least a few hours after birth that the right arm hung at the side and movement caused pain. The same condition was present when Dr. Brown operated several months later. When the humerus was rotated the head could be felt a little behind and under the acromion. The position of the wrist and fingers was partly flexion; the elbow could be flexed with a little force. Skiagraphs showed the head of the humerus out of place. Attempts to pull the bone into position were unsatisfactory. He then cut down upon the joint over the deltoid posteriorly, and on rotating the arm the head of the humerus snapped into the glenoid cavity. The wound healed kindly. There was still some spasmodic flexure of the hand. Photographs of the original condition showed prominence over the shoulder and pronation of the hand.

Infantile Athletics.—DR. HENRY LING TAYLOR read the paper. When one considered the muscular structure it became evident that man was not destined for a life of inactivity. The manner of obtaining an existence by ancient man, or man in the uncivilized state, necessitated much exercise, and at the present day we found ourselves with a physical system whose healthy function was not in harmony with rest. Growth itself implied exercise, and it was not without significance that fœtal movements began at least five months before birth, and the infant was ushered into the world with a cry. In waking hours its small limbs practised vigorous movements, an act superficially unimportant, but which was necessary to growth and power. Our purpose should be to encourage freedom of movement, but instead mothers swathed the baby in much fine linen and prepared the way for debility

and sickness. What a contrast between the bringing up of the baby carried and jolted on the back of the African mother and that of the baby raised under the restrictions of city life! It had been observed that in cities infants showed much more vigor at birth than they did a year or two later.

Dr. Taylor advocated short dresses at an early period, so that the little one could kick freely, two air baths daily, with play and romping, and rubbing, or washing and rubbing of the surface. The feet were better off without shoes or even stockings. The natural tendency to play should be encouraged in children, and long tasks should not be imposed upon them, as they tire much easier than grown people under work. The baby must not be encouraged to walk too soon before sufficient physical development had taken place, lest injury result. One author had suggested undue strain in some form as a cause of anterior poliomyelitis, which usually occurred before the third year. Young children needed freedom as well as guidance, and companionship with animals and nature. They should have large doses of country life.

Congenital Dislocation of the Shoulder; Its Diagnosis and Treatment.—Dr. A. M. Phelps read the paper. It contained the histories of six cases of congenital dislocation of the shoulder, in four of which reduction was effected by operation, in two without operation. The first case which he had operated upon came on from San Francisco in the spring of 1895. The patient was seen by a number of surgeons and orthopædists, all of whom said they had had no experience with the condition. The patient was a boy eight years old, and, according to the statement of the parents, the trouble with the arm had existed since birth. Dr. Phelps found all of the movements of the arm interfered with, and the position of the head of the humerus, backward of the glenoid cavity, interfered especially with placing the arm across the chest. The hand could not be carried to the mouth. Movements of the humerus were accompanied by movements of the scapula. The whole arm was rotated inward, the palm turned backward, the elbow protruded a little from the side of the chest, the head of the humerus presented a bony prominence below the spine of the scapula. Flexion and extension of the forearm were weak, pronation and supination were normal.

After consulting with Drs. Gibney and Morris, he cut down upon the bone, making a curved incision along the lower edge of the deltoid on the scapula, and turned the flap down. It was best, however, to curve the incision downward and turn the flap upward, as it would give better drainage. He found the posterior edge of the glenoid cavity gone, and the cavity was about two-thirds the normal size. He cut away a portion of the head of the humerus in order to fit it to the socket, cut away a portion of the redundant capsule posteriorly, replaced the bone, and put a stitch in behind to help retain it in place. A drainage tube was left in a week. The result had been satisfactory. He had reported the case at the orthopædic section of the academy, April, 1895. It would be noted that in this case, and in some of the others, a part of the edge of the glenoid cavity was gone, having apparently been broken off, and in one or two instances a fragment of the bone was found, facts which pointed to trauma as the cause of the dislocation. In the reader's opinion, the condition was probably not uncommon, and had passed as a paralysis. But the same efforts at delivery which might cause a paralysis might also cause the dislocation. Doctors ought always to examine children carefully after birth for this and other injuries or deformities. The two cases treated without operation were in children in the Post-Graduate Hospital. Five cases were of the left shoulder, whereas two of Scudder's were of the right shoulder. Whether this had any bearing upon etiology, he was unable to say.

Dr. L. W. Hubbard presented a patient who had come under his observation soon after Dr. Phelps reported his first case, and the latter at his request operated. He found it easy to map out the head of the humerus below the spine of the scapula. Following the operation suppuration took place, which necessitated a counteropening, and as a result of the scars motion was not so complete as it might otherwise have become.

Dr. Phelps remarked that the suppuration was due to some catgut which he used in the wound. He also called attention to the fact that there was in these cases shortening of the clavicle and scapula, compared with the other side.

Dr. Hubbard added that a neurologist had found some reaction of degeneration in the muscles of the arm in his case before operation, and this had disappeared subsequently. It seemed to have been due to some pressure neuritis, and replacing the bone in its normal position had relieved this. The case was a congenital one.

Dr. R. H. Sayre had seen one or two of the reported cases, and another in an infant in which the dislocation was manifest in a skiagraph. The head of the humerus had slipped back of the glenoid cavity. The motions were limited, and there was a certain amount of spastic contraction of the muscles. He inferred from the history that there had been considerable violence at birth. He thought there could be no question as to the advisability of operating when replacement could not be made and maintained without it.

Dr. A. P. Dudley said he had sent the first case to Dr. Phelps, the parents of the patient being friends of his, and when he had examined the patient it was his opinion that there was a dislocation. Doctors who had seen the patient before that were of opinion that it was one of paralysis. Dr. Dudley did not doubt that the injury had occurred during the delivery. He had seen the patient a year after Dr. Phelps operated, and had heard from the parents within two weeks. The boy was undergoing gymnastic training, and at present there was little difference in the use of the two arms.

Dr. Phelps said twenty-one cases had now been reported, six with operation, Dr. Gerster having reported one case with operation, Dr. Phelps four with operation. As stated, the two cases in which he had made reduction under ether without operation were in young children. This method promised success during the first year, although one case had been reported in which it had been successful at the fifth year.

When to Operate in Appendicitis. — Gersuny (*Therap. Woch.*, November 15, 1896) does not believe in indiscriminate operating, but restricts it to three forms of appendicitis: "1. Patients that demand intervention themselves, on account of persisting abdominal distress. 2. When the suppuration is of a progressive character and threatens perforation. 3. When the perforation has occurred and there is a general peritonitis, which cases require operation at once. He has cured two patients, four hours and twenty hours respectively after perforation. An operation is strictly contraindicated in cases of extreme heart weakness. In ordinary typical cases, rest, opium, and deprivation of food are sufficient treatment. In atypical cases all preparations must be made to proceed to an operation if it become necessary. When there is hope of spontaneous recovery, it is allowable to interfere, but when the danger is imminent it becomes our duty to interfere."

Surgical Suggestions.

Fracture of Lower End of Radius.—Dr. Roberts (*The American Journal of the Medical Sciences*, January, 1897) says, in writing of the treatment of fracture of the lower end of the radius, that the deformity must be overcome, even if great force be applied. One should grasp the metacarpus with one hand, the lower part of the forearm with the other. The thumb of the surgeon's hand which holds the metacarpus should be placed on the palmar surface of the carpal fragment of the radius, as it lies just behind the thenar eminence. Extension and counterextension are to be made for a moment; the hand should then suddenly be bent backward in strong dorsal flexion, and at the same instant the surgeon's thumb should push the lower fragment backward into place. This can be done in an instant, and does not require an anæsthetic. The reduction will be painful, but it is so sudden a manipulation that the patient does not require an anæsthetic. When the fragments are driven into place there will be noticed a grating sensation.

Cocaine Anæsthesia.—Dr. John A. Wyeth (*The Southern Clinic*) speaks as follows: "In operations upon the hands or fingers, as in opening phlegmons, a rubber tourniquet may be thrown around the base of the finger or the wrist, compression being sufficient to arrest entirely or very much retard the return of blood to the heart until the operation is over; then, in the line of the proposed incision, the cocaine may be used a little more recklessly than is advised in operating upon the body. So painful, however, is a phlegmon of the finger that I have made it a rule never to carry the needle through the inflamed integument, but to introduce it preferably upon the back of the finger, where the tactile sense is less, and to carry it beneath the skin to some point near the proposed line of incision, and inject the cocaine from the under surface. In this way complete anæsthesia may be obtained, and these painful swellings incised, evacuated, and dressed before the tourniquet is removed and sensation restored. It is important in loosening the tourniquet not to remove it entirely at once, but to allow the circulation to be restored only for a few seconds, then to tighten the tubing for four or five seconds, and repeat this until several minutes have elapsed before the constriction is finally removed. This precaution is taken to prevent the sudden passage of any excess of cocaine into the circulation. In operations upon the leg, the thigh, the forearm, or the arm, the same control of the circulation may be exercised by constriction of the limb between the wound of operation and the heart."

Gynæcological Complications of Gonorrhœa.—Dr. Thomas Moore Madden, of Dublin, Ireland, writes, in the *American Journal of Surgery and Gynecology*, November, 1896, as follows: "The greater prevalence of disease of this kind in hospital than in private practice is, I think, unquestionable, and is explicable by the unclean personal habits and neglect of prophylactic treatment too generally observable in the former class of patients. In some of the instances of the kind observed in my hospital, the disease was distinctly and immediately traceable to the recrudescence, under the stimulus of sexual intercourse, of an infection contracted prior to marriage by the patient's husband, and suffered to run on into an ignored chronic, slight, gleety discharge, containing those specific and still pathogenically active micro-organisms by which gonorrhœa is communicable. More usually, however, the infection so conveyed is not recognized until its remote consequences are brought under gynæcological observation, earlier non-detection in these cases being due, first, to the common occurrence of non-specific hemorrhagic discharges from the vulvo-vaginal mucous surfaces, as well as to their comparatively lax structure, owing to which it is that, save when the infective virus is exceptionally intense and is chiefly localized in the more sentient tissues of the vestibule and meatus urinarius, women thus affected seldom manifest those evidences of local inflammatory action—scalding in micturition, pain in coitus, glandular complications, febrile disturbances, etc.—which generally attend acute gonorrhœa in the male.

Cancroids of the skin surface are treated by Dr. Kuhn (*Gaz. Méd. de Paris*, January 30th) with a combination of chromic acid and arsenious acid in the proportion of one gram of the former to five centigrams of the latter. In case of ulceration of the lesion being already present, the proportion is decreased: no calming substance need be added, since ulceration produced by the chromic acid is not painful.

Treatment of Appendicitis.—I think that the preliminary treatment is often worse than useless, and that the measures adopted in the very beginning are of extreme importance as regards the prognosis. A common procedure is the administration of a large dose of morphine, which quiets the pain and relieves the distress of the patient, but masks all symptoms. This prevents the proper study of the early stage of the complaint, the stage which is the most important both as regards diagnosis and treatment. The question of the rapid or gradual increase in severity and the advent of sepsis are obscured by the opium treatment. A patient presenting himself with severe abdominal pain, whether he has fever, nausea, vomiting, prostration, and constipation, or not, should be suspected of having appendicitis. The most probable cause of sudden, severe, and not otherwise easily explained intra-abdominal pain, is appendicitis. Such a patient should be put to bed and thoroughly examined; very little opium or other anodyne should be given, but the patient must be kept at rest and most carefully watched. If the diagnosis can be made during the first six hours, and the patient can be kept under observation for six hours longer, the progress of the disease may tell the whole story. Certainly, in twenty-four hours from the beginning of the attack we may be able to decide not only as to the diagnosis, but as to the probable course and result of the case. In my opinion, many of the casualties in this disease are due to neglect of the precaution which I have just recommended. The earlier the choice can be made between operative and palliative procedures the better for the patient.—Dr. Charles McBurney, *Medical News*, December 12, 1896.

Pneumectomy.—F. Terrier in the *Progrès Médical* of December 12, 1896, reviews up to date this operation, which has been performed on man for tuberculosis, cancer, and pulmonary hernia. In tuberculosis the three successful operations reported were circumscribed lesions in otherwise sound lungs and bodies, and it is more than probable that they might have been cured without surgical intervention. Blok's patient died under his hands, and he committed suicide to escape criminal prosecution. Surgical intervention in neoplasms due to cancerous infection elsewhere has been unsuccessful, owing to the presence of several foci, which it was impossible to find and entirely exterminate. In two cases, when a cancer in the thorax wall had spread into the pleural cavity, Krönlein and W. Müller operated with success, although one patient relapsed four years later, when a second operation was performed, which was equally successful. In these cases the surgeon must not hesitate to resect the

number of ribs necessary to open up the intrathoracic extension of the neoplasm. In cases of hernia from stabs, etc., when the lung simply protrudes, to close mechanically the incision, all that is needed is to disinfect the wound as thoroughly as possible and suture the serosa. The reduction must be made as early as possible, and the opening closed if the tissues are not already degenerated. If they are, resection of the gangrenous portion and reduction of the pedicle is the only procedure. Two instances have given satisfactory results. In case of actual hernia, Tuffier incises the tumor, reduces the herniated lung with resection of the sac and *débridement* of the orifice, detaching the wound all around, and suturing the ring. Experiments on animals have shown that the partial and even total resection of a lung is possible and even easy in many animals, but Milton, of Georgia, he states, was the first to perform pneumectomy on man. The surgical operation most frequently required is for traumatic hernia with pulmonary parenchymatous complications.

Otitis Media.—Don't use the nasal douche to relieve "cold in the head." Don't allow the ear to ache for a whole week without performing paracentesis. Don't keep up long-continued syringing, moppings, etc.—Burnett.

Pyosalpinx.—Adhere to the suprapubic operation. The vaginal route does not fulfil the conditions of a complete operation.—Joseph Price.

Fractures of the Skull.—It is absolutely unfair to contrast the results of surgery to-day with those of the pre-antiseptic era. Rules then enforced are now entirely abrogated, and the methods of to-day would have made our ancestors protest most loudly. One respect in which we violate precedent is in our disregard, to-day, of the periosteum or pericranium. This is sacrificed without hesitation when found to be infected or torn, or lacerated beyond possibility of repair. A flap of scalp it is known, will adhere as kindly to denuded bone as to periosteum, and we have even learned that skin grafts can be applied and relied upon to adhere to this same bone—if not upon the same day a little later when granulations have appeared. In the various plastic operations necessitated about the head, we may also transplant flaps upon otherwise uncovered bone without the slightest hesitation. We have, furthermore, learned to treat fractures mainly in accordance with what we decide as to intracranial complications, or through what we can see either through the wound, if present, or through an opening intentionally made under antispetic precautions for purposes of exploration. It is even conceded to be better policy to remove fragments of bone whose vitality is uncertain, and to sacrifice ruthlessly any tissue injured or lacerated to such an extent that sloughing would probably occur, or so exposed as to have become necessarily infected.—Park, "*Surgery by American Authors*," vol. ii., p. 31.

On the Removal of Foreign Bodies from the Œsophagus.—The *Bulletin de l'Académie de Médecine*, December 8, 1896, notes that the cathode ray has been improved so much that the location of coins, etc., in the œsophagus has become an easy matter, and then by opening down to the œsophagus the foreign body can be palpated and manipulated upward (without making an incision into the œsophagus) until it can be reached through the mouth and withdrawn with a pair of Mathieu forceps with corrugated blades. Children often swallow foreign bodies with dimensions equal to fifteen millimetres; they are usually arrested at the narrowest portion of the œsophagus, and if the objects remain upright it is difficult to recognize their presence by the usual methods, if the children continue to drink and swallow and do not complain of pain. In these cases radiography is of the greatest advantage, as it shows the exact location of the object. An incision down to the œsophagus then will allow the object to be forced upward and extracted through the mouth, avoiding an incision into the organ and thus not interfering with alimentation afterward.

Eye Operations.—A convenient way of dressing the eye after an operation is to apply to the lashes and to the edges of the lids an ointment composed of ten grains of iodoform to one drachm of vaseline, and over this a pad of iodoform wool, kept in place by a carefully applied bandage: this dressing may be changed every day.—Hartridge.

To Dressers.—In every case you dress ask yourself the question why you do each and every one of the different steps of the dressing. Do not blindly follow directions. Try to get a clear conception of the object you have in view, and then be careful to observe whether this object is attained.—Gould.

Bubo.—Dr. Clifford Perry considers that the best treatment of non-suppurating buboes of chancrous origin is by the intraglandular injection of one-per-cent. solution of benzoate of mercury—a method of treatment first advocated by Welander, who claimed to have cured without suppuration fifty-six out of seventy-eight cases.

Multiple Papillomata Affecting Both Vocal Cords, in which the use of instruments was not desirable, were completely removed by using a spray of alcohol. The patient sprayed the larynx six times a day for over four months.—Bryson Delavan.

Surgery of the Appendix.—Already there are indications of the adoption of a compromise between the comparatively late operation of English surgeons and the immediate resort to operative interference of the Americans.—*Bristol Med.-Chir. Journ.*

Hot Water, besides assisting sterilization, relieves the pain of inflammation and limits the inflammatory process. Its use is indicated in severe injuries of the extremities, and its heat is antagonistic to septic germs. In acute prostatitis its use by rectal irrigation is very beneficial, also in some hemorrhoidal states and uterine disorders. In acute tonsillitis, gargling with water at 130 F. has been carried out with success.—*Zeits. f. Krankenpfl.*

Sequelæ of Herniotomy.—There are instances in which, after successful reduction by taxis or operation, acute symptoms still persist. In such instances the following conditions have been found to exist: (1) A strangulation of the bowel exists elsewhere. (2) It has become kinked or twisted upon itself. (3) The reduced gut lies within the abdomen *hors de combat* and paralyzed. Peristalsis is impossible and all the symptoms of obstruction persist. In such a case, if suspected, the abdomen should be opened and an artificial anus established in the damaged loop. (4) The gut has become gangrenous or perforated after reduction. (5) Acute peritonitis has followed. (6) Enteritis may follow, attended by diarrhoea (in which the stools may contain blood), by paroxysmal pain, by vomiting, by a sunken abdomen, and great prostration. (7) As remote effects of the operation may be mentioned obstruction symptoms, due to firm adhesions of the once-strangulated loop, to stricture of the bowel following cicatrization after ulcer, and to the fixing of the involved piece of gut into the form of a permanent loop by means of unyielding adhesions.—Frederick Treves, "*System of Surgery*," vol. ii., p. 709.

Acute Hemorrhagic Septicæmia in a physician from a post-mortem prick was cured by the twelfth day by injections of antistreptococcic serum. At first three and one-half cubic centimetres were injected every four hours, and after the eighth injection seven cubic centimetres were employed until twenty-eight in all had been given.—Balance *and* Abbott, *Brit. Med. Jour.*, ii., 1,033, 1896.

A Hot Spray of salt solution will be found invaluable in clearing the trachea after tracheotomy when the mucus has become thick and tenacious.—Leonard Dobson.

Transplantation of Lipoma.—An opera singer operated upon by Czerny for interstitial mastitis with adenoma had a lipoma removed at the same time from the lumbar region and transplanted in such a way that the absent breast would not be noticed in her professional work.—*Gaz. Hebd.*, January 3d.

Death from Chloroform.—Though I admit the necessity of the most scrupulous attention to the respiration, I feel confident that, to teach that the pulse may be neglected, must inevitably lead beginners into difficulty. I have in my own records four cases in which the pulse became imperceptible at the wrist at a time when respiration was being effectively performed.—E. H. Empley, M.B., *Hon. Anæsthetist, Melbourne Hospital.*

Raynaud's Disease.—In about one-fifth of all cases, other distinct nervous phenomena have been noted. Nervous shock not infrequently determines the onset. Hutchinson reports a case following on a heavy domestic bereavement. In one of my own cases, a slight emotional disturbance was sufficient to produce an attack.—A. M. Finch Noyes.

Paralysis of Respiration.—It would appear that when the respiratory movements suddenly cease, a period of ten or eleven minutes elapses before the cessation of the heart's action, and that resuscitation may take place seven minutes, and probably longer, after the complete cessation of respiratory movements. —A. V. M. Anderson.

Hot-Snare Tonsillotome.—The instrument devised by Dr. Gradle (*Journal of the American Medical Association*, September 26, 1896) is stronger than the ordinary snare cannula. The handle consists of two parallel bars eleven centimetres long, mounted in vulcanite blocks. A third block is fitted with lateral rings for sliding along the bars. This, fitted to two brass bars, operates the snare. Steel piano wire is used. The current is connected with the posterior ring.

Diagnosis of Psoitis.—Dr. Gangolphe points out a sign of psoitis, in connection with a suppurative case of traumatic origin. It is pain upon pressure over the lesser trochanter, a pain which is accompanied with swelling and œdema of the upper and internal portion of the thigh.—*Gaz. Méd. de Paris*, February 13th.

Anæsthesia.—In a word, surgery before and after anæsthesia was Galilee in storm and Galilee after the "Peace, be still."—Samuel Keith.

1. The inhalation of ether procures for the patient a more or less perfect immunity from the conscious pain and suffering attendant upon labor. 2. It does not, however, diminish the strength or regularity of the contractions of the uterus. 3. It sometimes increases them in strength and number. 4. The contraction of the uterus after delivery seemed perfect and healthy when it was administered. 5. Its employment not only saves the mother from pain in the last stage of labor, but also in some degree from the occurrence and consequences of the nervous shock attendant upon the delivery. 6. Its exhibiiton does not seem to be injurious to the child.—Professor Simpson.

It is dangerous to have the air too heavily charged. The record of chloroform accidents shows most cases plainly due to sudden inspiration of too heavily charged air. Chloroform must be mixed thoroughly with air. Pouring it upon a handkerchief or napkin does not necessarily secure this, and may be a very faulty and dangerous method. An Esmarch mask, a bottle arranged for dropping, gives the best results.—Theo. F. De Witt.

After all it matters little where the stuff was got, or who first actually inhaled it at Edinburgh. Simpson was the guiding spirit, and but for his indefatigable energy and boldness as a clinical experimenter, and his power and resourcefulness as an advocate, the discovery of chloroform might well have been still-born.—*British Medical Journal.*

OUR LONDON LETTER.

(From our Special Correspondent.)

MEDICAL AND CHIRURGICAL SOCIETY — MALARIAL PARASITE IN WEST AFRICAN FEVERS—PULSATING EMPYEMA—MEDICAL SOCIETY — INTESTINAL ANASTOMOSIS—SENILE DECAY.

London, March 26, 1897.

At the Medical and Chirurgical Society meeting, Surgeon-Captain Duggan read a paper on the parasite of malarial fevers at Sierra Leone, where he resided for two years, and examined the blood in nearly four hundred cases, and made a special study of fifty. He found parasites in the blood from the finger in every case. The parasite was a minute body of a ring shape and in a later stage it enlarged slightly and contained a few minute grains of pigment. In a fatal case he found sporulating forms in the blood from the surface of the brain; but he did not meet with this in freshly drawn blood from the finger except once or twice. The parasite is so small that it occupies only about a third of the red corpuscle; he counted five spores in one parasite. He found crescent forms after some days of fever. He found the tertian parasite only once and then in a man who had had malarial fever in the West Indies two years before. He never met with the quartan parasite. The appearances were similar to those described by Marchiafava in the summer-autumn fever of Rome. In dried and stained preparations of finger blood, a nucleolar body was sometimes seen at the periphery, and sometimes in the centre, and sometimes two could be seen.

Dr. Thin remarked that the West Coast fevers were much more fatal than those in the south of Europe, and this was perhaps due to a plurality of parasites. He said that on one occasion four out of five artisans died almost immediately after arrival in Sierra Leone, one being attacked on the second day and dying on the fourth. Quinine was a most valuable protective if regularly given. Dr. Manson mentioned Plehm's work in the Cameroons as similar to Captain Duggan's, and urged the importance of microscopic examination, as cases of severe malaria were formerly returned as sunstroke. He said the plan of discharging men after three days' hospital treatment, common in the army, was inadequate, for the parasite would again appear in the blood in about a week, so that the patients ought to remain two or three weeks in hospital, and if para-

sites persisted the patients should be sent home. He referred to transmission by mosquitoes, and said he had found the flagellated forms in the stomach of the insect. In his reply, Surgeon-Captain Duggan remarked that mosquitoes were scarcely essential, as they were not numerous in the fever districts of the West Coast, and appeared only for a short time in the year.

Dr. Samuel West read a paper on pulsating empyema, of which there are two kinds—intrapleural and extrapleural. The impression given varies, as does the explanation. In large effusions the general shock is such as may be felt through a solid growth or extensive pneumonia, and is more a shock than a pulsation. There is also a wave-like pulsation usually limited to one or two front intercostal spaces, and this is probably a surface wave of fluctuation. Distensive pulsation, such as is met with in a large abscess, is due to the fluid being contained in resisting walls under tension, and in such cases thickening and rigidity of the lung and mediastinum are found at the post-mortem. It is these last cases which are the most fatal, for the changes are such as to prevent recovery.

Intestinal anastomosis has again been before the Medical Society, where Mr. Harrison Cripps related three cases, and spoke in favor of careful stitching and against bobbins and buttons, which he regarded as sometimes the cause of avoidable deaths. In this he was supported by Mr. Sheild, who preferred to dispense with apparatus and trust to his fingers and silk sutures. A paper was also read by Dr. Savill on senile decay, in which he dealt with normal and abnormal symptoms of old age, but Dr. Clifford Allbutt would not admit that the changes described were physiological and incidental to old age. Some of them were certainly such as he had once described clinically under the title of "Senile Plethora."

OUR PARIS LETTER.

(From our Special Correspondent.)

PROFESSOR DIEULAFOY—HIS GREAT WORK ON INTERNAL PATHOLOGY—THE HÔTEL DIEU—APPENDICITIS A SURGICAL DISEASE—DISCUSSION BY PROFESSORS LUCAS-CHAMPIONNIÈRE, JALAGUIER, AND RECLUS—PRESENTATION TO THE ACADÉMY OF MEDICINE—HOW THE HOSPITAL IS SUPPORTED, ETC.

PARIS, April 1, 1897.

THE Hôtel Dieu is the principal hospital of Paris—that is, the most important, not only from a professional but also from a bureaucratic standpoint. It is in the Hôtel Dieu that the professors at the Faculty of Medicine of Paris graduate, so to speak, or finish as professors of clinic the careers that they began years before as *professeurs agrégés*. In other words, a clinical professorship there is the highest medical position in France—there exists none beyond. The words used by Professor Dieulafoy (of whom and his remarkable work on internal pathology we propose to speak in this letter), in his inaugural address to the students, on the occasion of his entrance into the Hôtel Dieu as professor of clinic, were these: "To-day the faculty causes me to climb the supreme round." They are only confirmatory of what is already acknowledged regarding this exalted medical position.

The present Hôtel Dieu is built upon the site of the old one, and dates from 1865, although the inauguration did not take place until July 28, 1877. It is a massive pile, consisting of granite or gray stone of that formation, and occupying the whole of a large block; one main building fronting on the Parvis Nôtre Dame, with the other, the rear building, on the Seine, the portico and entrance into the spacious courtyard being on the Nôtre Dame side. This courtyard is divided into two by a second portico or bridge of granite connecting the several wings on either side of the vast edifice; those on the right as one enters being devoted to female, those on the left to male wards. At the farther end of this second courtyard is the church, built in the Greek style, likewise of granite, where mass is said every Sunday morning, which the inmates of the hospital have the privilege of attending. Besides the main front and rear buildings there are three additional ones, running from one side street to the other, and forming six wings, with always the same disposition regarding distribution of male and female wards—all the buildings being two stories high. The class of diseases treated at the Hôtel Dieu is general—that is, embracing all medical and surgical diseases; patients are allowed to receive visits from friends on Thursdays and Sundays, from one to three o'clock; and those in danger of death, constantly. M. Joret, the director, informed me that the annual expenses of the hospital average about 1,302,718 francs. According to the last budget issued, that of 1895, the number of inmates was, on the 1st of January, 621; during the year, 10,923; 9,557 had left the hospital; there had been 1,203 deaths, and there remained 784. The number by (365) days of all those treated, including out-patients, was 352,403. It should be noted that the Hôtel Dieu with its annex accommodates 800 indoor patients.
